Shearing Effect.—Although the effect of shear is seldom noticeable in an ordinary column, yet it becomes quite apparent in a short block or cube of stone, cement, or other granular material when tested in compression. The sides of the block flake away, often leaving the broken specimen like a shattered pyramid or cone. The same shearing stresses which rupture the block of stone are undoubtedly present in complex form in any column, but our means of analysis are limited. If, instead of the stone, we select a short block of wood, with the grain in the direction of the pressure, the shearing will be along the grain, or planes of least resistance, although the tendency to shear will be along sloping, pyramidal planes.

If, now, a sheet of lead is interposed between the stone cube and one of the platforms of the testing machine the flaking of the stone will be more pronounced, due to the spreading or lateral expansion of the lead as it is flattened against the stone.* This illustrates in an exaggerated way how the material in any column tends to spread out under pressure, and weaken the resistance to shear.

Fig. 1.

Notation for Column Formulas:

- A = area of column section, in sq. ins.;
- I = moment of inertia of section in ins. = $A r^2$;
- r = radius of gyration of section in ins. = $\sqrt{I/A}$;
- d = least diam. of rectangular section, in ins.;
- d_0 = diameter of round column, in ins.;
- P = total load on column, in lbs.;
- p = load per sq. in. on column = P/A ;
- y = distance, in ins., of most strained fiber, from neutral axis;
- v = lateral deflection of column in ins., under load P ;
- e = eccentricity of loading on columns, in ins.;
- f_c = compressive stress in lbs. per sq. in. = $P/A + p$;
- f_b = bending stress, outer fiber, in lbs. per sq. in. = $Pvy/I = pvy + r^2$;
- f = max. outer fiber stress, comp. + bending, in lbs. per sq. in. = $f_c + f_b$;
- f_e = f at the elastic limit of the material;
- f_u = f at the ultimate strength of the material;
- f' = f at any assignable value, for distinction;
- E = modulus of elasticity of material, in lbs. per sq. in.;
- l = effective length of column, in inches
- L = effective length of column, in feet;

$$a = \text{value of } p \text{ in Euler's formula for long columns} = \frac{\pi^2 E r^2}{l^2} = \frac{\pi^2 E}{144 L^2} :$$

In which $\pi = 1$ for 2 pivot ends — established by Euler,
 $\pi = \frac{1}{2}$ for 2 pin ends — established by Johnson,
 $\pi = \frac{1}{4}$ for 1 pivot, 1 fixed — established by Euler,
 $\pi = \frac{1}{8}$ for 1 pin, 1 flat — established by Johnson,
 $\pi = \frac{1}{2}$ for 2 flat ends — established by Johnson,
 $\pi = 4$ for 2 fixed ends — established by Euler.

* For this reason sheets of lead or other soft material are now considered objectionable in testing machines; and, by some, on masonry abutments under bridge shoes or pedestals.

Short Strut—Direct Compression Only.—By a short strut whose length is not over, say, 12 or 15 times its diameter or less. For such a column we have the formula:

$$f = \frac{P}{A} \dots \dots \dots$$

$$\text{Whence } P = fA \text{ and } A = \frac{P}{f} \dots \dots \dots$$

Short Strut—Eccentric Loading.—The usual formula for the stress f in a short column eccentrically loaded, is

$$f = \frac{P}{A} + \frac{Pey}{I} = \frac{P}{A} \left(1 + \frac{ey}{r^2} \right)$$

it being assumed that the column is braced laterally, as in building, against falling over; and furthermore that there is appreciable lateral deflection v . If lateral deflection were not taken into account we would have

$$f = \frac{P}{A} + \frac{P(e+v)y}{I} = \frac{P}{A} \left[1 + \frac{(e+v)y}{r^2} \right] \dots \dots \dots$$

Long Columns—Bending Only.—The following formulas and conditions of long columns, bending only, are adapted from Euler and T. H. Johnson.

Euler's Formulas:

$$2 \text{ Pivot Ends } \left\{ \begin{array}{l} P = \frac{\pi^2 EI}{l^2} = \frac{\pi^2 EI}{144 L^2} \\ p = \frac{\pi^2 Er^2}{l^2} = \left(\frac{\pi r}{l} \right)^2 E = \left(\frac{\pi r}{12L} \right)^2 E \end{array} \right.$$

1 Pivot,
1 Fixed

2 Fixed Ends

$$\left\{ \begin{array}{l} P = \frac{16\pi^2 EI}{9 l^2} = \frac{\pi^2 EI}{81 L^2} \\ p = \frac{16\pi^2 Er^2}{9 l^2} = \left(\frac{4\pi r}{3l} \right)^2 E = \left(\frac{\pi r}{9L} \right)^2 E \end{array} \right.$$

$$\left\{ \begin{array}{l} P = \frac{4\pi^2 EI}{l^2} = \frac{\pi^2 EI}{36 L^2} \\ p = \frac{4\pi^2 Er^2}{l^2} = \left(\frac{2\pi r}{l} \right)^2 E = \left(\frac{\pi r}{6L} \right)^2 E \end{array} \right.$$

Fig.

Johnson's Formulas:

$$2 \text{ Pin Ends } \left\{ \begin{array}{l} P = \frac{5\pi^2 EI}{3 l^2} = \frac{5\pi^2 EI}{432 L^2} \\ p = \frac{5\pi^2 Er^2}{3 l^2} = \frac{5}{3} \left(\frac{\pi r}{l} \right)^2 E = \frac{5}{432} \left(\frac{\pi r}{L} \right)^2 E \end{array} \right.$$

1 Pin, 1 Flat

2 Flat Ends

$$\left\{ \begin{array}{l} P = \frac{25\pi^2 EI}{12 l^2} = \frac{25\pi^2 EI}{1728 L^2} \\ p = \frac{25\pi^2 Er^2}{12 l^2} = \frac{25}{12} \left(\frac{\pi r}{l} \right)^2 E = \frac{25}{1728} \left(\frac{\pi r}{L} \right)^2 E \end{array} \right.$$

$$\left\{ \begin{array}{l} P = \frac{5\pi^2 EI}{2 l^2} = \frac{5\pi^2 EI}{288 L^2} \\ p = \frac{5\pi^2 Er^2}{2 l^2} = \frac{5}{2} \left(\frac{\pi r}{l} \right)^2 E = \frac{5}{288} \left(\frac{\pi r}{L} \right)^2 E \end{array} \right.$$

Fig.

There is one peculiar feature about the preceding formulas, namely, that they do not take into consideration the compressive (nor the shearing) resistance of the material, but simply the bending resistance or stiffness of the column. Hence they give excessive values for the loads P or p . Euler attempted to remedy this defect by placing an upper limit to the value of p , equal to the compressive resistance f_c of the material. This is illustrated in Fig. 5, a diagram showing the (elastic) strength of steel columns with pivoted ends.

Fig. 5.

Ritter's Formula for Columns.—The following formula was proposed by Ritter in 1873 and has been worked out by others later. Although very ingenious and possessing considerable merit the reasoning by which it is deduced is not considered strictly rational and it takes its place with all other formulas in this respect. The equation of the elastic strength of columns is

$$p = \frac{P}{A} = \frac{f_c}{1 + \frac{f_c l^2}{\pi^2 E r^2}} = \frac{f_c}{1 + \frac{f_c}{n a}} \quad \dots \dots \dots (11)$$

The curve of this formula, for pivoted ends, is platted in Fig. 5. The method of applying a factor of safety to formula (11) is

$$p = \frac{f}{1 + \frac{f'}{n a}} \quad \dots \dots \dots (12)$$

in which f is considered to be the working stress of the material, and f' any value between the working stress and the ultimate stress. It is to be noted that with f constant, the factor of safety increases as f' increases, but not proportionately. Strictly speaking, the formula applies only within the elastic limit of the material, i. e., when f' (and f) do not exceed f_c . The value of f' should be above any possible value of f , and should always be greater than $2f$ for maximum static loading, or its equivalent. Again, with $f > f_c$ the factor of safety is greater for long columns than for short.

Author's Formula for Columns.—From mechanics, $f = f_c + f_b = \frac{P}{A} + \frac{Pvy}{I} = p \left(1 + \frac{vy}{r^2} \right)$, whence

$$p = \frac{P}{A} = \frac{f}{1 + \frac{vy}{r^2}} \dots \dots \dots (13)$$

Again, the bending moment at center of column is

$$M = Pv \dots \dots \dots (14)$$

But according to Euler, $P = \frac{\pi^2 EI}{l^2}$, whence (14) reduces to

$$v = \frac{M}{P} = \frac{Mp}{\pi^2 EI} \dots \dots \dots (15)$$

Substituting this value of v in equation (13) we have

$$p = \frac{f}{1 + \frac{My}{I} \left(\frac{p}{\pi^2 EI} \right)} = \frac{f}{1 + \frac{My}{naI}} \dots \dots \dots (16)$$

From the theory of flexure, we have,

$$M = \frac{I}{y} fb = \frac{I}{y} (f - f_c) = \frac{I}{y} \left(f - \frac{P}{A} \right) = \frac{I}{y} (f - p) \dots \dots \dots (17)$$

Whence, by substitution, equation (16) reduces to

$$p = \frac{f}{1 + \frac{f - p}{na}} = \frac{f}{\left(1 - \frac{p}{na} \right) + \frac{f}{na}} \dots \dots \dots (18)$$

So far, our reasoning seems to be correct, but when we attempt to solve equation (18) we find that $p = f$ or na . From an examination of the last form of equation (18) it will be seen that the first term p , equal to the load per sq. in. on column, would be decreased by substituting unity for the quantity $\left(1 - \frac{p}{na} \right)$ in the denominator, and hence would be on the side of safety. Moreover, it would reduce to Ritter's formula (12), by making $f = f$; thus, $p = \frac{f}{1 + \frac{f}{na}}$. But from the above discussion, we are certain that, for any

column of given length l , $p < na$, and $\left(1 - \frac{p}{na} \right) < \text{unity}$. Assuming tentatively the value of Ritter, $p = \frac{f}{1 + \frac{f}{na}}$, in order to arrive at an approximate

value of $\left(1 - \frac{p}{na} \right)$ in the second form of equation (18), we have $p + \frac{pf}{na} = f$; whence, by transposition, $p = f - \frac{fp}{na}$, or $1 - \frac{p}{na} = \frac{p}{f}$; and this substituted in equation (18) gives

$$p = \frac{f}{\frac{p}{f} + \frac{f}{na}} \dots \dots \dots (19)$$

This reduces still further to

$$p = f (\sec \theta - \tan \theta) \dots \dots \dots (20)$$

the desired formula; in which $\tan \theta = \frac{fe}{2na}$.

In using formula (20), find

1st. The value of $\sqrt{\tan \theta}$, from Table 1, on the following page.

2nd. The corresponding value of $\sec \theta - \tan \theta$, from Table 2.

3rd. Multiply this last value by f to obtain the allowable load p per sq. in. on column; f being the allowable working stress per square inch for a short column.

Thus, by the use of Tables 1 and 2, the value $(\sec \theta - \tan \theta)$ in equation (20) can be transformed into a numerical quantity, or decimal factor. See Examples, page 592.

EXAMPLES IN THE USE OF TABLES 1 AND 2.

[From Column Formula, $p = f (\sec \theta - \tan \theta)$, equation (20).]

Ex. 1.—Find the safe load, factor 4, of a medium-steel z-bar column with flat ends, whose length is 26 ft., sectional area 24.8 sq. ins., and radius of gyration 2.6.

Solution.—From Table 1, $\sqrt{\tan \theta} = .058 \frac{L}{r} = .58$; and from Table 2, the corresponding value of $(\sec \theta - \tan \theta) = .72$; hence the safe working load $p = .72 \times 15\,000 = 10,800$ lbs. per sq. in., and the total safe load $= 10\,800 \times 24.8 = 267\,840$ lbs.

Ex. 2.—Find the safe load, factor 5, of a vertical post of Douglas spruce in a Pratt steel combination highway bridge, said post being 12×14 ins., 28 ft. long, and with pin end bearings.

Solution.—The value of f for Douglas spruce (col. 4, Table 7, page 495) is 1400. From Table 1, $\sqrt{\tan \theta} = \frac{1}{5} \cdot \frac{28}{14} = .933$; and from Table 2, the corresponding value of $(\sec \theta - \tan \theta)$ is .456; hence total allowable load $P = .456 \times 1400 \times 12 \times 14 = 107\,251$ lbs. (See also Table 3.)

Ex. 3.—What load would be carried by a column similar to that in Ex. 2, but with flat ends?

Solution.—Table 1: $\frac{1}{5} \cdot \frac{28}{14} = .747$; Table 2 equivalent $= .588$; hence $P = .588 \times 1400 \times 12 \times 14 = 138\,288$ lbs.

Gordon's Formula for Columns.—Probably no other formula has been so universally accepted as that of Gordon—sometimes called Rankine's formula. Adopting the previous notation, it is deduced as follows: The maximum outer fiber stress due to both compression and bending is

$$f = \frac{P}{A} + \frac{Pvy}{I} = \frac{P}{A} \left(1 + \frac{vy}{r^2} \right) \dots \dots \dots (21)$$

whence
$$\frac{P}{A} = p = \frac{f}{1 + \frac{vy}{r^2}} \dots \dots \dots (22)$$

Now the deflection v of the column is an unknown quantity, but Gordon assumed it to be proportional to $\frac{P}{y}$, which assumption would be allowable if the total fiber stress f were due to *bending only*. Substituting this proportional equivalent of v in equation (21) and supplying the coefficient c whose value is to be determined by experiment, we have the general form:

$$p = \frac{f}{1 + \frac{P}{c y^2}} \dots \dots \dots (23)$$

For the working formula, the value assigned to f is usually the ultimate strength per sq. in. of a short column of the material, divided by factor of safety, as 4, 5, 6, etc. The coefficient c is an arbitrary constant determined by trials in fitting the curves of the formula to platings from actual tests of strengths of columns up to the points of failure, and making $f = \text{ult. strength} \div \text{factor of safety}$. (See Secs. on *Bridges* and *Buildings* for special application of Gordon's formula; also the tables following under this section.)

C. Shaler Smith's Formula for Wooden Columns.—This formula gives values much too low for long columns. It is reproduced here more for its historical, than for its actual working value. The formula is as follows:

$$p = \frac{f}{1 + .004 \frac{l^2}{d^3}} \dots \dots \dots (24)$$

the ultimate strength of white pine being assumed at $f_s = 5000$. The ends of the column are to be flat and firmly fixed; with concentric loading.

Straight-Line Formulas.—Curved-line formulas, previously explained, may be reduced to straight-line formulas by finding the equation of the tangent to the curve at the point of contra-flexure. Thus, in Fig. 5, page 590, c is the point of contra-flexure of the curve, and its tangent at that point cuts the coordinate axes of the diagram at T and t ; the resulting straight-line formula for the elastic strength of the steel column with pivot ends thus reducing to

$$p = 35\,400 - 169 \frac{l}{r} \dots \dots \dots (25)$$

in which $35\,400 = 1.18 f_e = 1.18 \times 30\,000$; E being assumed at 30 000 000 in the present instance. If now this tangent is swung slightly on the point c so that the point T is lowered to 34 000, it will practically fit the curve for a long distance, with the resulting equation

$$p = 34\,000 - 150 \frac{l}{r} \dots \dots \dots (26)$$

Same kinds of timber apply to round columns as to square—
see to left.

Notation:

L = length of column in feet;
 l = length of column in inches;
 d = least width of rectangular column in ins.;
 d_o = diameter of round column in ins.

* Points of equality of values in table with values deduced from approximate straight-line formula.
 † Maximum excess of values from straight-line formulas over those of table; 8.7% for square, 8% for round columns.
 ‡ For Rectangular Columns, use d for least dimensions, in ins.

Steel Columns.—From the preceding discussion of Column Form might readily conclude that, for a column of given sectional area and length l , that column is the strongest which has the greatest radius of gyration r . But this is not always true. To illustrate: On page 604, Fig. 26, we find the properties of the Hollow Circle, of outside diameter d and inside diameter d_1 , giving $r = \frac{\sqrt{d^2 + d_1^2}}{4}$ and $A = 0.7834 (d^2 - d_1^2)$.

if we let A remain constant and gradually increase d_1 from zero until it approach d , which must also gradually increase, but less rapidly than r likewise increases in value from $r = 0.25 d$ (when the column is a circular cylinder) up to its maximum limit $r = 0.3535 d$ (when the column becomes a cylindrical shell whose thickness approaches zero). It is quite apparent that before the maximum limit of r is reached, the column will fail through *auxiliary* or *secondary stresses*, set up in the metal shell, causing it to buckle and collapse.

The *Secondary Stresses*, above described, may be provided against either (1) Making the metal thick enough, throughout, to withstand buckling; (2) Providing longitudinal ribs, as in the case with the Phoenix column, Table 11, page 604 and other standard built-up columns, in which the ribs are (3) Inserting (transverse) diaphragms at intervals along the column, done with very large sections.

Where Columns are Latticed, or where stay-plates are simply independent (unsupported) portion should be calculated as a column with its own radius of gyration.

Column Sections may be made up as follows:—

- (A). —Two angles riveted back to back, forming a T-section.
- (Aa). —Same as (A), but with round fillers or a plate riveted between the angles, giving a greater radius of gyration.
- (B). —Four angles and a web plate, forming an H-section, similar to the rolled H-Column of Table 14, page 608. The distance between the angles should be in whole or half inches, and from 12 to 18 inches greater than width of web plate.
- (Ba). —Same as (B), but with the addition of two channels riveted back to back of the angles, with flanges of channels projecting inward.
- (Bb). —Same as (B), but with lattice bars instead of web plate.
- (C). —Two channels and two plates, as per Fig. 6, below. See also pages 8, 9, and 10, pages 661, etc.
- (Ca). —Same as (C), but with latticing instead of plates—one or both sides.
- (Cb). —Same as (C), but with flanges of channels projecting inward, and latticing or stay plates instead of cover plates.
- (D). —Same as (C), (Ca) and (Cb), but with plate and two angles riveted back to back of channel.
- (E). —Z-bar column. See Tables 6 and 7, pages 598, etc.

Also other sections made up of a combination of these shapes.

To find the movement of inertia, I , and the radius of gyration, r , for any column section, see Example, page 627, in connection with Tables 3 and 4, pages 639, etc.

The *Channel Column*, Fig. 6, is standard for all classes of construction. The following table gives the standard dimensions:

4.—CHANNEL COLUMNS—STANDARD DIMENSIONS IN INCHES.

Depth of Channel C	Width of Plate P	W	R	$W + R$	E

**—TOTAL SAFE LOAD IN THOUSAND POUNDS FOR Z-BAR COLUMNS
(WITHOUT SIDE PLATES.)**

t = thickness of metal;

A = area of cross-section of column;

w = weight of column in lbs. per lin. ft., not including weight of rivets;

r = least radius of gyration.

Allowable stresses per sq. in.: safety factor 4: $\left\{ \begin{array}{l} 12,000 \text{ lbs. for lengths of 90 radii or under;} \\ 17,100 - 57 \frac{l}{r} \text{ for lengths over 90 radii.} \end{array} \right.$

(See opposite page for Dimensions.)

Problem.—A column composed of 2 8-in. channels at 16.25 lbs. and 2 plates 10×⅞ ins. will support a load of 249,700 lbs. up to 21.7 ft. in length. Find the load that it will support if 30 ft. long?

Solution.— $249,700 \text{ lbs.} \times \frac{21.7}{30} = 46,600 \text{ lbs.}$

Answer 209,100 "

† Lattice bars not less than 1¼"×⅝". ‡ Lattice bars not less than 2"×⅝".

11.—* PHOENIX STEEL COLUMNS.

Dimensions, Properties and Loads.

"The dimensions given in the following table are subject to such slight variations as are unavoidable in the manufacture of these shapes.

The weights given are those of the segments composing the columns, and from 2 to 5 per cent must be added for weight of the rivet heads.

The safe loads specified are computed as being one-fourth of the ultimate, or breaking loads, and as producing a strain, or pressure, in an axial direction on square-end columns, of not more than 12,000 lbs. per square inch for lengths of 90 radii and under.

The A, B1, B2, and C columns have each 4 segments, the E have 6, and the G have 8 segments.

Any desired thickness between the minimum and maximum can be furnished.

$$\text{Least Radius of Gyration} = D_0 \times 0.3636.$$

12.—ULTIMATE AND SAFE ($\frac{1}{8}$) STRENGTHS OF HOLLOW ROUND AND HOLLOW RECTANGULAR CAST IRON COLUMNS.

In the following formulas, $U = 80\,000$ and $S = 10\,000$ lbs. per sq. in.:

$$p = \frac{\text{Square Ends } U \text{ or } S}{1 + \frac{(12L)^2}{800d^2}} = \frac{\text{Square \& Pin } U \text{ or } S}{1 + \frac{3(12L)^2}{1600d^2}} = \frac{\text{Pin Ends } U \text{ or } S}{1 + \frac{(12L)^2}{400d^2}} = \frac{\text{Square Ends } U \text{ or } S}{1 + \frac{3(12L)^2}{3200d^2}} = \frac{\text{Square \& Pin } U \text{ or } S}{1 + \frac{9(12L)^2}{6400d^2}} = \frac{\text{Pin Ends } U \text{ or } S}{1 + \frac{3(12L)^2}{1600d^2}}$$

L = length of column in feet; d = (least) outside diameter in inches;
 p = load in lbs. per square inch on column to produce U or S .

$\frac{L}{d}$	Round Columns. Loads in 1000 lbs. per square inch.						Rectangular Columns. Loads in 1000 lbs. per square inch.

Safe loads given in the table are equal to one-eighth the ultimate loads, that is, using safety factor 8. If the safety factor 10 is preferred the *new* safe load may be found from the *ultimate* load by moving the decimal point one place to the left.

13.—SAFE ($\frac{1}{2}$) LOADS ON HOLLOW ROUND CAST IRON COLUMNS WITH FLAT ENDS

By Formula $P = \frac{10\,000A}{1 + \frac{(12L)^2}{800d^2}}$; in which $\left\{ \begin{array}{l} P = \text{total load on column in 1000 lbs.} \\ A = \text{sectional area of column in sq.in.} \\ L = \text{length of column in feet.} \\ d = \text{outside diam. of column in ins.} \end{array} \right.$

Reinforced Concrete Columns.—The following working stresses for static loads are recommended by the Special Committee of the Am. Soc. C. E., on Concrete and Reinforced Concrete. See Trans. A. S. C. E., Vol. LXVI., page 452. For Notation and Formulas, see Sec. 25, Masonry, page 446. For working stresses for Beams, see Sec. 31, page 585.

Average compressive strength of concrete—2000 lbs. per sq. in. at 28 days, when tested in cylinders 8 ins. in dia. and 16 ins. long, under laboratory conditions of manufacture and storage.

Bearing.—See page 585.

Axial Compressions.—(A). For concentric compression on a plain concrete column or pier, when the length does not exceed 12 diameters, 450 lbs. per sq. in. on 2000-lb. concrete may be allowed. (B). Columns with longitudinal reinforcement only, 450 lbs. per sq. in. on 2000-lb. concrete. (C). Columns with reinforcement of bands or hoops, 540 lbs. per sq. in. on 2000-lb. concrete may be allowed. (D). Columns reinforced with not less than 1% and not more than 4% of longitudinal bars and with bands or hoops, 650 lbs. per sq. in. for 2000-lb. concrete. (E). Columns reinforced with structural steel column units which thoroughly encase the concrete core, 650 lbs. per sq. in. for 2000-lb. concrete.

Reinforcement.—In all cases, longitudinal steel is assumed to carry its proportion of stress; and the compressive stress shall not exceed 16000 lbs. per sq. in. or 15 times the working compressive stress in the concrete. Hoops or bands are not to be counted upon directly as adding to the strength of the column. Bars composing longitudinal reinforcement shall be straight, and shall have sufficient lateral support to be securely held in place until the concrete has set. When bands or hoops are used, the total amount of reinforcement shall not be less than 1% of the volume of the column enclosed. The clear spacing of such bands or hoops shall not be greater than one-fourth the diameter of the enclosed column. Adequate means must be provided to hold bands or hoops in place so as to form a column with a straight and well-centered core. Bending stresses due to eccentric loads must be provided for by increasing the section until the maximum stress does not exceed the values above specified.

EXCERPTS AND REFERENCES.

Reinforcement of Concrete Columns (By E. P. Goodrich. Eng. News, July 19, 1906).—"Consider reports that spiral steel is 2.4 times as effective as longitudinal reinforcement of equal weight, and this figure was closely checked by v. Bach, of Stuttgart."

Table of Weights of Lacing for Steel Compression Members (By C. T. Lewis. Eng. News, Aug. 2, 1906).—Weights are in lbs. per lin. ft. of single- or double-laced member on *one side*; the depths of member ranging from 5" to 23", and the size of lacing bars from 1½"x½" to 3"x½". Rivets, ½" to ¾".

Table of the Various Column Formulas in Use (Eng. News, Jan. 3, 1907).—Comprises formulas of the Rankin type for steel and cast iron; of the straight-line type for steel, cast iron and timber; and of miscellaneous type for timber: with an equivalent reduction, for all formulas, to a formula having a factor of eccentricity e . Interesting as a study.

Detachable Form for Concrete Columns (By W. S. Coulter. Eng. News, Mar. 28, 1907).—Illustration and description. When building reinforced concrete columns, having flexure rods united at intervals by ties, forms are often used having one side open, which is built up in sections as the concrete is deposited. These forms usually consist of four or more uprights enclosed on three sides, the fourth being open to allow access to the interior, and closed as the work proceeds by horizontal boards nailed to the uprights. Through the open side all the operations of depositing, spading and tying are conducted. The present device is intended to facilitate the work of erection and expedite the placing of the concrete.

Table of Tests of Carbon-Steel and Nickel-Steel Columns, and Comparison with Formulas (By C. P. Buchanan. Eng. News, Feb. 13, 1908).—Table gives actual strength and computed strength of columns. The computed strengths are from the following formulas:

- (1) Dagron's tests (steel cols.) compared with..... $P = 61000 - 263 \frac{l}{r}$
 - (2) Waddell's tests (nickel-steel) compared with..... $P = 47000 - 178 \frac{l}{r}$
 - (3) Buchanan's tests (steel) compared with..... $P = 79000 - 388 \frac{l}{r}$
- In which P = computed strength in lbs. per sq. in.; and l and r the length and radius of gyration, in ins. (See, also, Eng. News of April 9, 1908.)

Safe Stresses in Steel Columns (By J. R. Worcester. Trans. A. S. T. M., Vol. LXI).

Tests of Reinforced Concrete Columns at Minneapolis, Minn. (By J. G. Houghton and W. P. Cowles. Eng. News, Dec. 3, 1908).—The tested had the following kinds of reinforcement: Spiral wire circular flat-bar bands; wire bands, square; wire bands, circular. Columns were made of 1:2:3½ concrete, using bank sand and blue limestone. One-half of the stone being of ¾-in. size and one-half of pea size. Reinforced columns averaged about 25% stronger than the plain columns, though 5 of the 17 failed at lower loads than the plain columns.

Preliminary Program of Tests of Steel Columns (Proc. A. S. T. M., Vol. VIII., 1908).—Types of sections selected for testing, at Watertown: (a) Annular section (welded tubes); (b) New wide flange H section; (c) section of four angles and central web-plate; (d) Double-channel section latticed in two planes. Also other shapes. Illustrated. "Some results of the tests," by J. E. Howard, may be found on pages 336 to 344, same issue of Proc.; also Vol. IX., 1909, page 413.

Tests of Plain and Reinforced Concrete Columns (By M. O. Proc. A. S. T. M., Vol. IX., 1909).—Tables and diagrams.

Tests of Plain and Reinforced Concrete Columns (By M. O. Proc. A. S. T. M., July 1, 1909; Eng. Rec., July 10, 1909).—Conclusions derived from the tests: 1. A small amount, ¼ to 1%, of closely spaced reinforcement, such as the spirals used, will greatly increase the tensile and ultimate strength of a concrete column, but does not materially affect the yield point. More than 1% of lateral reinforcement does not appear to be necessary. The use of lateral reinforcement alone does not seem to be profitable. 2. Vertical steel in combination with such a lateral reinforcement raises the yield point and ultimate strength of the column and increases its stiffness. Columns reinforced with vertical steel only are brittle and fail suddenly when the yield point of the steel is reached, but are considerably stronger than plain columns made from the same grade of concrete. Increasing the amount of cement in a spirally reinforced column increases the strength and stiffness of the column. A column made of rich concrete and mortar and containing small percentages of longitudinal and lateral reinforcement is without doubt fully as stiff and strong and more economical than one made from a leaner mix reinforced with considerably more steel. In these tests doubling the amount of cement increased the yield point and ultimate strength of the columns without vertical steel about 100% and about 50% to the strength of those with 6.1% vertical steel. 3. The behavior of the columns reinforced with spirals and vertical steel, under load, and the results computed, it would seem that a static load equal to 30% of the yield point would be a safe working load. As the ultimate strength of the concrete and the yield point of the steel are generally known, it may be assumed with fair accuracy, formula (A) can be readily used to determine the safe working load. In Fig. 7 the dotted lines represent working load $P+A$ equal to 40% of the yield point load. (See original article for details of A and Fig. 7). 4. The results obtained from tests of columns reinforced with structural steel indicate that such columns have considerable strength and toughness and that the steel and concrete core act in unison up to the yield point of the former. The shell concrete will remain intact up to the yield point of the steel is reached, but no allowance should be made for the strength or stiffness. 5. As many of the blotters on the tops and sides of columns bore imprints of the vertical steel after failure, it would be a safe precaution to use bed plates at the foundations for such columns, thus prevent any possibility of the steel punching through the concrete under an excessive load.

33.—STRUCTURAL DETAILS.

The handbooks published by the various steel manufacturers are now pretty well standardized, and are indispensable to constant designers and detailers of structural work. The writer aims to keep this volume abreast of the most approved practice in the design of ordinary structures.

Rivets.—In the '80's, iron rivets began to give way to steel rivets in engineering structures, and now the latter are universally employed. The best rivet steel is a soft steel whose tensile strength varies not more than a few thousand pounds from 53 000 lbs. per sq. in.; the manufacturer's standard specifying 48 000 and 58 000 as the lower and upper limits. Higher grades of steel are more liable to fracture both in driving and afterward when subjected to repeated stresses in the structure.

Note.—Bearing values above or to right of upper zigzag line of pair are greater than double shear. Values between upper and zigzag lines of each pair are less than double and greater than single. Values below or to left of lower zigzag line of each pair are less than shear.

PROBLEM IN RIVETED JOINTS.

(Reference to Tables 1, 2, 6; and to Figs. 5, 6, 29.)

Example.—Let it be required to design a flat steel bar, spliced at n with a chain-riveted joint (Fig. 29, page 617), to resist a tensile stress of 69600 lbs.; as per following data.

Data.—Assume rivets in single shear at 10000 lbs. per sq. in. and bearing value for plates at 20000 lbs. per sq. in. (see Table 1, above). Assume allowable tension on net area of splice plates and bars, at 17500 lbs. per sq. in. (see Figs. 5 and 6, in Table 2, for pitch, etc., of rivets.)

Solution.—

Allowable total stress on bar and joint

Rivets in shear (Table 1): Eight $\frac{3}{4}$ -in. rivets in double shear

$$= 8 \times 2 \times 4420 = 70720$$

Rivets in bearing on splice plates (Table 1): Two $\frac{1}{2}$ -in. plates

$$= 8 \times 2 \times 4080 = 65280$$

Rivets in bearing on main bar (Table 1): One $\frac{3}{4}$ -in. bar

$$= 8 \times 9380 = 75040$$

Tension on main bar: $\frac{3}{4} \times 17500 \times 6\frac{1}{4}$ (net width of bar in ins.)

$$= 69730$$

Transverse width in bar occupied by holes (see Note to Table 6):

$$3(\frac{3}{4} + \frac{1}{8}) = 2\frac{1}{4}$$

Total width of bar (or splice plate) required for stress

$$= 6\frac{1}{2}(\text{net}) + 2\frac{1}{2}(\text{holes}) = 9 \text{ ins.}$$

Natural spacing of rivets on transverse section of bar and splice

$$= 9 + 3 = 3 \text{ ins.}$$

(This pitch is allowable, from Table 2, second column.)

Distance from center of rivet to edge of plate

$$= (9 + 2) - 3 = 1\frac{1}{2} \text{ ins.}$$

(This is allowable, from Table 2, and Fig. 6.)

Distance between centers of rows of rivets (Table 2): $3 \times \cos 30^\circ = 2\frac{1}{2} \text{ ins.}$

Distance from centers of rivets to ends of bars or plates:

$$\text{not} < \frac{1}{2} \text{ pitch } \frac{P}{2} = 1\frac{1}{2} \text{ ins.}$$

Length of splice plates: $1\frac{1}{2} + 2\frac{1}{2} + 2\frac{1}{2} + 1\frac{1}{2} + 1\frac{1}{2} + 2\frac{1}{2} + 2\frac{1}{2} + 1\frac{1}{2} = 16\frac{1}{2} \text{ ins.}$

REMARKS ON TABLES 3 AND 4.

The advantage of using standard rivet gages and connections is the saving of time in both the drafting room and in the shop. In detailing a building, the first step is to get out the erection drawings, showing diagrams of columns, floor plans, sectional elevations of complicated and special connections, and all sizes and dimensions from previous calculations of design. Each member of the structure is numbered for the convenience of the detailer, the shop and the erection gangs. The detailing begins with columns and then proceeds with the girders, beams, etc.

Caution.—For special heavy and short beams the erection drawings should show special connections, if required.

4.—STANDARD CONNECTION ANGLES FOR I-BEAMS AND CHANNELS.

For 24" Beams.

Ls 4"x4"x $\frac{1}{8}$ "x1' 6" Ls 4"x4"x $\frac{3}{8}$ "x1' 6"

Fig. 14.

For 20" Beams.

Fig. 21.

Note.—In the above illustrations, two systems of connection angles are shown, that of the Carnegie Steel Co. being on the left, and Cambria on the right, in each case. Legs showing shop rivets are riveted directly to ends of I-beam or channel, while those showing field rivets are for field connection. Angles are riveted on in pairs. A play of $\frac{1}{8}$ of an inch is allowed at each end of the built member between the back of angles and the girder to which it is to be connected in the field.

Screw Bolts for Timber and Metal.		Hook Bolt for Bridge Work.	
Square Head and Nut.		Hexagonal Head and Nut.	
Figs. 34, 35.		Fastening Guard Rail and Tie to Girder.	
		Fig. 36.	

Stone Bolts for Bridge Work.

Diam. of hole = diam. of bolt + $\frac{1}{4}$ ".

Length of wedge for split bolt = $3d$; width = d ; thickness at head = $\frac{1}{2}d$; point rounded.

Swedged, Split. Screw.

Swedge Bolts. (Fig. 37.)

- $\frac{3}{4}$ " x 9", Wt. = 2 $\frac{1}{2}$ lbs.
- $\frac{1}{2}$ " x 12", Wt. = 3 $\frac{1}{2}$ lbs.
- 1" x 12", Wt. = 4 $\frac{1}{2}$ lbs.
- 1 $\frac{1}{4}$ " x 15", Wt. = 7 $\frac{1}{2}$ lbs.

Anchor Bolts for Concrete

Screw bolts (Figs. 34, 35) with flat washers; middle of bolt deflected 1 dia. before setting.

Figs. 37, 38, 39.

8.—STANDARD SCREW THREADS.

(Sellers; Franklin Institute, Dec., 1864; United States, 1868.)

Fig. 40.		$\frac{7}{8}$	.731	9					6	5.423	27				

Note.—The Pitch is $\frac{1}{N}$; and the flat f , at top and bottom, is $\frac{1}{8N}$.

In the Whitworth or English standard the angle of thread is 55° instead of 60° ; the top and bottom of threads are rounded; and N is 12 for $D = \frac{1}{2}$, otherwise N is the same as above for D up to 3 inches.

9.—DIMENSIONS AND WEIGHTS OF HOT PRESSED NUTS.

The sizes are the usual manufacturers', not the Franklin Institute Standard. Both weights and sizes are for the unfinished nut.

(Dimensions in ins.; weights in lbs.)

Size of Bolt.	Rough Hole.	* Square Nuts.				† Hexagon Nuts.				
		Side of Square.	Diagonal.	Wt. of 100 Nuts.	No. of Nuts in 100 lbs.	Thickness of Nut.	Short Diam.	Long Diam.	Wt. of 100 Nuts.	No. of Nuts in 100 lbs.

THE USE OF LAG SCREWS.

The principal use of lag screws is for bridge work—in fastening one timber down on another. They are better than spikes, but not as good as screw bolts (with nut and head.)

The lag screw has a square head and is screwed in place with a wrench. A plate washer is used under the head to distribute the bearing stress on the timber.

A hole is first bored in the timber, somewhat smaller in diameter than the screw, the lag screw is inserted in the hole and tapped on the head a few times with a sledge hammer, and then screwed to a firm bearing with the wrench.

Caution. The writer has used lag screws for fastening small wooden guard rails (4"x8") to wooden ties. When such work is being done, especially by contract, there should be an inspector on the work to see that the lag screws are not hammered into the timber too far with the sledge hammer before the wrench is used. To the contractor, hammering is much the cheaper and is a great temptation.

Separators for 18, 20 and 24 in. beams are made of $\frac{5}{8}$ in. metal.

Separators for 6 to 15 in. beams are made of $\frac{1}{2}$ in. metal.

Separators for 5 in. beams and under are made of $\frac{3}{8}$ in. metal.

REMARKS ON CAST IRON SEPARATORS.

The use of cast iron separators and bolts for fastening two or more I-beams together, side by side, is gradually giving place to steel diaphragms, composed of angles riveted to a connecting web plate. The latter is much the better, and is now preferred in important steel building construction. Cast iron separators, however, are still used in connecting steel I-beams in grillage foundations, where spaces between the beams are filled with concrete.

Cast separators for timber work are round, of cylindrical or spool shape, with a hole through which the screw bolt passes. They are used principally for packing, between lines of wooden bridge-stringers, spacing the wooden stringers about one inch apart. This spacing provides for the circulation of air, which dries the moisture from rain and retards rotting of the wood. Cast spool separators are shaped like a spool, while the cylindrical separators are perfectly cylindrical on the outside. In order to save metal, in the separator, the hole expands towards the ends, being a little larger than the bolt, only, at middle of separator.

REMARKS ON CAST AND PLATE WASHERS.

Cast iron washers are used principally with screw bolts in connection with timber work. They are round and have a diametric section as shown in Fig. 47. These washers are sometimes called *O. G.* washers, or *S* washers, because the outline curve has an *O. G.* (architectural term) or *S*, shape, being a reversed curve.

Large, square, cast iron washers are often used for anchorage at the ends of rods in concrete.

Plate, or flat, washers are stamped from sheet metal, being round with a hole in the center for the bolt. Large bolts require the thicker washers, that will not bend when the bolt is tightened.

REMARKS ON SPIKES AND NAILS.

Steel wire spikes and nails are made from steel wire, being cut, and pointed by machine. They may be either plain (smooth) or bar added holding power).

Cut spikes and nails have greater holding power than the smooth wire, because they have a rougher surface to give the greater friction.

Tests on the holding power of railway spikes were made by Mr Webber, Instructor of Civ. Eng., Univ. of Ill., and the results are given in Bulletin No. 6, issued by the Experiment Station. The tests were on spikes and plain spikes: direct pull and lateral displacement.

It is to be noted that the variation in weight of spikes and nails is considerable, even for the same sizes.

t 1 inch expansion per 100 ft. of bridge. The rollers should (shown in above cut) for mean temperatures; and hence the equal to, and even a little greater than, half the expansion.

Brace Problem.—The following solution of the "Howe problem" is one which the writer devised and has used exten-

Fig. 61, let the length of panel (generally is between chords) = $2h$, center side (generally the $2p$. Let x and y be the center of end (point width = $2d$. With h and d constant the scribe a circle of radius the origin o .

$= d^2 \dots \dots \dots (1)$

p constant and d variable will trace the curve oso' , which is derived as folloetry the angles a and a_1 at $\tan a = \frac{y}{x}$, and $\tan$

equating,

$= \frac{p-x}{h-y}$

$= p'x - x^2$

Fig. 61.

and if p is less than h ,

$$y = \frac{h}{2} - \sqrt{\left(\frac{h}{2}\right)^2 - x(p-x)} \dots \dots \dots (2)$$

Combining the equation of the circle (1) and of the equilateral hyperbola (2) analytically is a complex process and unnecessary in solving the values of x and y .

By inspection, Fig. 61, it will be seen that as the point s approaches the origin o (as the width of brace decreases) the angles α and α_1 increase, and when s reaches o $\tan \alpha = \tan \alpha_1 = \frac{p}{h}$. That is to say, the equation of a straight line tangent to the hyperbola at the origin o is

$$y' = \frac{p}{h} x' \dots \dots \dots (3)$$

Fig. 62.

Plotting this line (see Fig. 62), we know very nearly where the point s is on the circle (1). It will be just below and close to it. Then solving equation (3) for two values of x , on either side of and near s will give, without appreciable error, the tangent to the hyperbola at s , and the intersection of this tangent with the circle will be the point s .

Example: Let height of truss = 20 ft. clear between chords; panel length = 12 ft.; width of brace = 14 ins.; then, reducing to inches, $h = 120$, $p = 72$, $d = 7$. With o as origin plot circle (1) with d as radius, full size; also lay off tangent, equation (3), intersecting the circle at T . The point s will lie a little below T on the circle. Assume $x_1 = 6$, then, equation (2), $y_1 = 60 - \sqrt{3,600 - 396} = 3.40$. Assume $x_2 = 6\frac{1}{4}$, then equation (2), $y_2 = 60 - \sqrt{3,600 - 410.94} = 3.52$.

Plot $x_1 y_1$ and $x_2 y_2$; connect with line intersecting circle at s . Then, by scale, $x = 6.09$ ins., $y = 3.45$ ins. $A s B$ is face of angle block. Length of brace is

$$2 \sqrt{(h-y)^2 + (p-x)^2} = 22 \text{ ft. } 3\frac{1}{4} \text{ ins.} +. \text{ Ans.}$$

***Tables of Cubes and Squares.**—The subjoined tables of cubes and squares are very useful in designing and detailing. For convenient reference they are listed as follows:

Table 31.	—Cubes of Inches,	0" to 9",	advancing by 64ths and 32ds.
31a.	— " " "	9" to 29",	" " 16ths.
31b.	— " " "	29" to 109",	" " 8ths.
32.	—Squares of Inches,	0" to 12" (0' to 1'),	advancing by 64ths.
32a.	— " " "	12" to 120" (1' to 10')	" " 32nds.
32b.	— " " "	120" to 624" (10' to 52')	" " 16ths.

Note that the last column of Table 32b, ($+\frac{1}{16}$), is the average amount (the amount at the center of the respective line—the half-inch column) to be added for each 32nd of an inch. Thus, the square for $13' 0\frac{1}{2}"$ is 24472.69; and for $13' 0\frac{1}{4}"$ is $24472.69 + 9.78 = 24482.47$. The same result can also be obtained by adding the squares of $13' 0\frac{1}{2}"$ and $13' 0\frac{1}{4}"$ together, and dividing the sum by 2; thus, $(24472.69 + 24492.25) \div 2 = 24482.47$. Remember that this difference ($\frac{1}{16}$) is for the $\frac{1}{2}$ "-column, in middle of line; and that for the beginning of the line the tabular difference in the last column should be decreased by 0.03, and increased by 0.03 for end of same line. This refinement, however, of modifying the amounts given in the last column, to conform to different parts of the line, may generally be neglected.

Explanation of Uses of Tables 31 to 32 b.—These tables may be used in finding bending moments, moments of resistance, moments of inertia and radii of gyration; and in the solution of right angle triangles when two sides

*These tables are abridged from those in the writer's forthcoming structural handbook.

are given, and of any triangle when three sides are given. The following examples will illustrate.

FINDING BENDING MOMENTS. (Table 32b.)

Example.—A girder having a span (L) of $14' 5\frac{1}{4}"$ supports a uniform load (W) of 400 lbs. per lin. ft. What is the bending moment (M'') in in.-lbs.?

Solution.—From the well-known formula $M'' = \frac{12WL^3}{8}$, we have, if l = span in ins. $= 12L$, $M'' = \frac{WP^3}{12 \times 8} = \frac{400 \times 30080.6}{12 \times 8} = 125336$ in.-lbs. Ans.

FINDING RESISTING MOMENTS. (Table 32a.)

Example.—What is the resisting moment in inch-lbs. (M'') of a rectangular beam 6" wide (b) and $12\frac{3}{8}"$ deep (d), assuming the allowable fiber stress per sq. in. (f) = 1000 lbs.?

Solution.—From the well-known formula $M'' = \frac{1}{6} f b d^2$, we have, by substitution, $M'' = \frac{1000 \times 6 \times 165.766}{6} = 165766$ in.-lbs. Ans.

FINDING RADII OF GYRATION.

The square of the radius of gyration (r^2) = the moment of inertia (I) divided by the area (A) of the section. Thus $r = \sqrt{I + A}$.

FINDING MOMENTS OF INERTIA.

Example. — Fig. 63 represents the section of a steel column latticed on two of its sides. Find the moments of inertia about the axes X and Y .

Solution.—The moment of inertia (I) of a rectangle about its base, is $I = bh^3 + 3$; in which b = width and h = height of rectangle. Hence, $3I = bh^3$. Now, Fig. 63 is symmetrical about each of its axes, hence if we find the value of $3I$ for one-quarter of the section and then increase this value by one-third, we obtain the value $4I$ for one-fourth of the section = I for the whole section. The calculation is tabulated below; the values of bh^3 being made up from the various rectangles in one-quarter of the section.

Fig. 63.

bh^3 about axis X .

bh^3 about axis Y .

30" plate.	$\frac{1}{3} \times (15)^3 = + 2320.31$	15" $\times (10\frac{5}{8})^3 = + 16450.65$
17 1/2" plate.	$\frac{5}{8} \times (8\frac{3}{4})^3 = + 418.70$	$15" \times (9\frac{7}{8})^3 = + 13375.00$
6" angle.	$6 \times (15\frac{1}{2})^3 = + 20760.48$	$8\frac{3}{4} \times (9\frac{7}{8})^3 = + 7802.08$
"	$- 5\frac{3}{4} \times (14\frac{1}{2})^3 = - 16386.36$	$8\frac{3}{4} \times (9)^3 = + 6378.75$
"	$- \frac{5}{8} \times (9\frac{7}{8})^3 = - 474.88$	$6 \times (9\frac{7}{8})^3 = + 5350.00$
		$5\frac{3}{4} \times (9)^3 = + 3918.38$
		$5\frac{3}{8} \times (3\frac{7}{8})^3 = - 29.77$

$+ 6638.25$
 Add one-third— 2212.75

$+ 5900.83$
 1966.94

For the whole section, $I_x = 8851.00$

$I_y = 7867.77$

Another Method.—Instead of using the "rectangle method" (preceding case), we may use the method of "transference of neutral axis." Thus, to find the moment of inertia of the $17\frac{1}{2} \times \frac{5}{8}$ plate about the axis Y we proceed as follows: Find I_o about its own neutral axis ($I_o = b h^3 + 12 = 17\frac{1}{2} \times (\frac{5}{8})^3 + 12 = 0.356$) and then use the formula $I_y = I_o + A a^2$, in which A = area of plate = $17\frac{1}{2} \times \frac{5}{8}$, and a = distance between the two axes (see Fig. 63). Hence, the moment of inertia of the plate about the axis $Y = I_y = I_o + A a^2 = 0.356 + 17\frac{1}{2} \times \frac{5}{8} \times (9\frac{1}{4})^2 = 948.88$. Proceed in like manner with the other plates, and the angles, etc. The sum of the several moments of inertia will be the total moment of inertia of the section.

Corollary.—In the last method, above, we have the equation, $I_y = I_o + A a^2$. When the section of the column is unsymmetrical, it is often necessary to assume an axis Y and find the value of I_y about this axis, and then, from the said equation, to find the values of a and I_o .

SOLVING RIGHT ANGLE TRIANGLES. (Tables 32, 32a, 32b.)

Example.—What is the hypotenuse of a right angle triangle whose base is $21' 7\frac{1}{2}"$ and perpendicular $38' 9\frac{1}{4}"$? ($h^2 = b^2 + p^2$.)

Solution.—From Table 32b we have:

For square corresponding to	$21' 7\frac{1}{2}"$	=	67340.25
" " " "	$+ 38' 9\frac{1}{4}"$	=	16.22
" " " "	$38' 9\frac{1}{4}"$	=	216515.70
		=	283872.17
Ans.	$44' 4\frac{1}{4}"$	=	283855.9

Corollary.—From the above equation, $h^2 = b^2 + p^2$, it is evident that $b^2 = h^2 - p^2$ and $p^2 = h^2 - b^2$.

SOLVING ANY TRIANGLE—3 SIDES GIVEN.

Example.—In Fig. 64 let there be given the sides H , h and $B + b$. Solve the triangle.

Solution.—Drop the perpendicular p upon the base $B + b$. Then, $p^2 = H^2 - B^2 = h^2 - b^2$; therefore, $H^2 - h^2 = B^2 - b^2$.

$$\text{Whence, } B - b = \frac{H^2 - h^2}{B + b}.$$

$$\text{And } B = \frac{B + b}{2} + \frac{B - b}{2},$$

$$\text{And } b = \frac{B + b}{2} - \frac{B - b}{2}.$$

Fig. 64.

Problem.—Given the three sides of a triangle (Fig. 64): $h = 14' 3\frac{1}{4}"$, $H = 28' 7\frac{1}{2}"$, and $B + b = 35' 6\frac{1}{2}"$. Solve for the left-hand angle at the base (which call θ)?

Solution.—Using the formulas in the solution to the above Example, we have,

$$H = 28' 7\frac{1}{2}"; H^2 \text{ (ins.)} = 118078.1$$

$$h = 14' 3\frac{1}{4}"; h^2 \text{ (ins.)} = 29433.7$$

$$\therefore H^2 - h^2 \text{ (ins.)} = 88644.4; \log = 4.9476513$$

$$B + b \text{ (ins.)} = 426.50; \log = 2.6289190$$

$$\text{diff.} = 2.3177323$$

$$\therefore B - b \text{ (ins.)} = 207.84; \log = 2.3177391$$

$$2) 634.34$$

$$\therefore B \text{ (ins.)} = 317.17; \log = 2.5012921$$

$$H \text{ (ins.)} = 343.625; \log = 2.5360848$$

$$\text{diff.} = 9.9652073$$

$$\text{Ans.} — \theta = 22^\circ 37' 46", \text{ from } \log \cos \theta = 9.9652076$$

EXCERPTS AND REFERENCES.

Direct Method of Spacing Rivets and Finding Position, etc., of Stiffeners in Plate Girders (By E. Schmitt. Trans. A. S. C. E., Vol. XLV).

Diagrams for Determining Minimum Alternate Spacing of Rivets (By F. L. Batchelder. Eng. News, Oct. 31, 1901).—This diagram is very simple to construct for any diameter of rivets, and is based on the general equation, $a^2 = x^2 + y^2$.

A Table for Pitch and Efficiency of Riveted Joints (By P. B. Hill. Eng. News, July 16, 1903).—For various thicknesses of plates and diameters of rivets.

Standard Heads for Machine Screws (By H. G. Reist. Eng. News, June 29, 1905).—Illustrations and table of dimensions of screws with round head, filister head, flat head and hexagon head. (Also see Eng. News, Dec. 28, 1905, for table of standard threads for machine screws and taps, for $\frac{3}{8}$ " diameter and less; also, Eng. News, June 20, 1907, for A. S. M. E. standards.)

Tension-Tests of Steel Angles with Various Types of End-Connection (By F. P. McKibben. Proc. A. S. T. M., 1906; Eng. News, July 5, 1906).—Table shows percent strength of material developed: usually from 75 to 80%. (See, also, Eng. News, Aug. 22, 1907.)

Cost of Shop Drawings for Structural Iron and Steel (By R. H. Gage. "The Technograph," Univ. of Ill., No. 21, 1906-7; Eng. News, Aug. 8, 1907).—Condensed as follows:

Type.	Character of Building.	Av. Cost per Ton.
A.	Entire skel. cons.; loads all carried to found'n by steel columns	\$1.45
B.	Exterior supported on steel cols.; floor loads carried by exter. walls	1.22
C.	Inter. portion sup. by cast iron cols.; fl. lds. by exter. walls	.70
D.	No cols.; floor beams resting on masonry walls throughout	.85
E.	Structure consisting mostly of roof trusses resting on columns	2.47
F.	Structure consisting mostly of roof trusses resting on mas. walls	1.25
G.	Mill buildings	2.56
H.	Flat one-story shop or manufacturing buildings	.74
I.	Tipples, mining- or other complicated structures	4.88
J.	Malt or grain bins and hoppers	2.47
K.	Remodeling and additions where measurements are necessary before details can be made	1.87

The Detailing of Skew Portals (By J. P. Davies. Eng. News, Feb. 11, 1909).—Formulas, diagrams and shop detail drawings.

Diagrams for Rivet Pitch in Loaded Girder Flanges (By P. L. Pratley. Eng. News, Feb. 18, 1909).—Formulas and diagrams.

Tests of Nickel Steel Riveted Joints (By A. N. Talbot. Eng. Rec., Aug. 20, 1910).—Gives details and results of tests made for the Board of Engineers of the Quebec Bridge. Illustrations of the joints tested, and tables of the results of the tests. Table 3 (not reproduced here) gives the ultimate strength of the nickel steel joints, and of the carbon steel joints (tested in 1905 by Am. Ry. Eng. & M. W. Assn.) reported in lbs. per sq. in. of the shearing area of the rivets. The average for the nickel steel joints is seen to be about 16% greater than for the carbon steel joints. It should be noted that the rivets of the nickel steel joints are considerably weaker than the plates and that the failure of these joints was due in all cases to shear of rivets, while in the carbon steel joints there was evidently less inequality between the strength of rivets and of plates, a number of joints failing by tearing the plate.

Formulas for Use in Detailing Steel Structures (By H. Vance. Eng. News, Sept. 1, 1910).—Examples: Hoppers, towers and oblique bends in riveted pipe.

column 1, 7° means 0000000, 2° means 00, etc. The thickness of metal
2, 3 and 4 is based on the weight of iron in avoirdupois ounces per
sq. ft. in column 5, assuming the weight of iron at 480 lbs. per cubic foot.
self-explanatory, steel being assumed 2 per cent heavier than iron.
per cent either way from the above weights is usually allowed.
is per square foot to kilograms per square meter, mult. by 4.8824.
is per square foot to kilograms per square meter, mult. by 0.4536.
is per square foot to pounds per square meter, mult. by 10.7639.
Multiply the tabulated weight of iron by 1.133; for brass, mult. by 1.07;
9; for lead, mult. by 1.47; for aluminum, mult. by 0.347. All some-
See also Standard Gages, Table 1, preceding.

35.—CORDAGE, WIRE AND CABLES.

Technical Cordage Terms.

MAKE UP (IN MANUFACTURE):

Yarn.—Fibers twisted together.	<i>Marline</i> .—Two yarns twisted together.	
	<i>Thread</i> .—Two or more small yarns twisted together.	<i>Cord</i> .—Several threads twisted together.
	<i>String</i> .—Two or more slightly larger yarns twisted together.	
	<i>Strand</i> .—Three (by some authorities two) or more large yarns twisted together.	<i>Rope</i> .—Several strands twisted together. <i>Hawser</i> .—Large rope of three strands.
		<i>Shroud laid</i> .—Rope of four strands (with a heart). <i>Cable</i> .—Three hawsers twisted together (left handed).

A ROPE IS:

Laid.—By twisting strands together in making the rope.

Spliced.—By joining to another rope by interweaving the strands.

Whipped.—By winding yarn or small stuff around the end to prevent unstranding.

Served.—When wound tightly or continuously with yarn or small stuff.

Parceled.—When served or wrapped tightly with canvas.

Seized.—When two parts are bound tightly together by yarn or small stuff.

Payed.—When painted, tarred or greased to resist wet.

PRACTICAL OPERATION:

Haul.—To pull on a rope.

Taut.—Drawn tight or strained.

Bight.—A loop in the rope.

Fall.—The rope in a hoisting tackle.

Tackle.—An assemblage of ropes and blocks.

Hitch.—Attaching a rope to an object.

Bend.—Attaching two ropes together or to an object.

Knot.—A loop or fastening with a rope.

Knots, Hitches, etc.—(See *Manila Rope*, next page.)

(Note that Ends are whipped to prevent unstranding.)

Fig. 16, Timber Hitch and Half Hitch.

Fig. 17, Round Turn and Half Hitch.

Fig. 18, Blackwall Hitch.

Fig. 19, Fisherman's Bend.

Splices.—To splice an ordinary transmission rope, wind twine around the rope the length of the proposed splice, say 6 ft. or more, from each end, and unlay the strands back to the twine. Then butt the ropes together so that the untwisted strands will meet opposite each other in pairs. Next, cut the twine and unlay one strand from one rope end, following it up with a strand from the other rope end, and leaving about 18 or 20 ins. loose end on each strand at the *meeting point*, for sub-splicing. Make the points of meeting of other pairs of strands staggered regularly so no two points will be opposite. For sub-splicing of each pair of strands, split each strand, unlay and interweave, passing the ends through the rope, or tie with ordinary knots. Hammer smooth.

Manila Rope.—(Adapted from C. W. Hunt.*) Manila rope is made from Manila hemp fibers (inferior in strength to the Italian hemp). In manufacturing rope, the fibers are first spun into a yarn about $\frac{1}{4}$ in. in diam. this yarn being twisted in a "right-hand" direction. From 20 to 80 of these yarns, depending on size of rope, are then put together and twisted in a "left-hand" direction, into a strand. In a 3-strand rope three, and in a 4-strand rope four, of these strands are then twisted together, again in a "right-hand" direction. Note that when *each strand* is twisted it tends to untwist the threads, but later when the strands are twisted *together* into a rope, each strand tends to untwist, but to twist up the threads. It is this opposite twist of the threads and strands that keeps the rope in its proper form.

The *durability* of Manila rope is quite variable under different uses. Experience has shown that 4-strand rope is more serviceable than 3-strand; it is stronger for the same diameter, wears rounder and smoother, and the section is much nearer a circle.

The **Strength and Weight of Manila Rope** are given by Mr. Hunt in the following formulas:

Breaking strength, in pounds	=	$7160 \times (\text{diam in inches})^2 \dots\dots (1)$
	=	$725 \times (\text{circum in inches})^2 \dots\dots (1a)$
Weight per lineal foot, in pounds	=	$0.34 \times (\text{diam in inches})^2 \dots\dots (2)$
	=	$0.0344 \times (\text{circum in inches})^2 \dots\dots (2a)$

* See *Manila Rope* by C. W. Hunt; also Trans. Am. Soc. M. E., Vol. xii, p. 280, and Vol. xxiii (1901).

Hence, from (1) and (2) we have:

Breaking strength (lbs.) = 21060 × weight per lineal foot (lbs.) (3)

It is to be noted from formula (3) that pound for pound, manila rope is as strong as steel which has an ultimate tensile strength of 71600 lbs. per square inch: as a square inch bar of steel weighs 3.4 lbs. per lineal foot, and $21060 \times 3.4 = 71600$ lbs.

1.—WEIGHT AND STRENGTH OF MANILA ROPE. (By SLIDE RULE.)

* The left-hand figures in the column are the weights according to Mr. Hunt's formula (2), and the right-hand figures are corrections which give resulting weights in accordance with some of the manufacturers' tables. The true weights are somewhat approximate and probably lie within the two limits.

† Calculated from Mr. Hunt's formula. See also table of Breaking Strength of Manila Rope by Spencer Miller in *Eng. News*, Dec. 6, 1890.

The safe strength of manila rope given in the above table is based on a safety factor of 20, which Mr. Hunt recommends for rope driving. The following working loads are recommended for rapid (400 to 800 feet per minute), medium (wharf and cargo, hoisting 150 to 300 feet per minute), and slow (derrick, crane and quarry, speed at 50 to 100 feet per minute) work:

2.—WORKING LOAD FOR MANILA ROPE.

Diameter of Rope, Inches.	Ultimate Strength, Pounds.	Working Load in Pounds.			Minimum Diameter of Sheaves in Inches.		
		Rapid.	Medium.	Slow.	Rapid.	Med'm.	Slow.

*This table was calculated on a basis of 483.84 lbs. per cubic foot for steel wire. Iron wire is a trifle lighter.

The breaking strains were calculated for 100,000 lbs. per sq. in. throughout, simply for convenience, so that the breaking strains of wires of any strength per square inch may be quickly determined by multiplying the values given in the table by the ratio between the strength per square inch and 100,000. Thus, a No. 15 wire, with a strength per square inch of 150,000 lbs., has a breaking strain of $407 \times \frac{150,000}{100,000} = 610.5$ lbs.

It must not be thought from this table that steel wire invariably has a strength of 100,000 lbs. per sq. in. As a matter of fact it ranges from 45,000 lbs. for soft annealed to over 400,000 lbs. per sq. in. for hard wire.

†This table gives the strength of wire at the rate of 70.3 kilograms per square millimeter, which is equivalent to 100,000 lbs. per sq. in. and was calculated on this basis simply for convenience. Steel wire may have a tensile strength from 30 to 300 kilograms per square millimeter, according to treatment, composition, etc.

—(Adapted from Roebling.) Wire rope is made of wires *laid together*, which is the most common form, or (2) *laid* other, as employed in cables of large suspension bridges. or stranded rope may be either (a) *round* or (b) *flat*. The each commonly composed of 4, 7, 12, 19 or 37 wires twisted in the opposite direction to the twists of the strands into

rope is composed of a number of wire strands twisted around or around a wire strand or wire rope. Standard wire rope is strands and a hemp core practically of the same size. But uses 4, 5, 7, 8, 9 or any reasonable number of strands may be strands are twisted around the core to the right the rope is "right lay," and if to the left "left lay." When wires and strands are same direction the resulting rope is called "lang" rope. The form the more flexible rope, and for great flexibility the ropes may consist of wire ropes, as in tiller ropes. Generally, the ropes are saturated with tar, providing little additional strength but on to preserve the shape of the rope and helping to lubricate the rope-strand or wire-rope core will usually add from 7 to 10 per cent of the length of the rope, but, excepting in stationary ropes, the wear on the rope is as rapid as the outside wear of the rope. For ships' running ropes, where great pliability is demanded, as well as to reduce friction, the strands are made of 12 or 18 wires twisted together.

A rope consists of a number of strands laid side by side in alternate right and left lay, and sewed together with annealed wire so as to form a rope usually from $\frac{3}{8}$ to $\frac{1}{2}$ inch in thickness, and from 1 inch to 4 inches in diameter. (The sewing wires wear out and have to be renewed.) This kind of wire rope is specially adapted for long and deep shafts, under which conditions it possesses advantages over a rope which has a tendency to twist and untwist.

Composing wire ropes and cables are usually of steel or iron; for special purposes they are sometimes made of copper, bronze, or brass. The strength of iron wire ranges from 45,000 to 100,000 lbs. per sq. in. The strength of steel employed are open-hearth steel with an ultimate strength of 50,000 to 130,000 lbs. per sq. in.; crucible steel from 130,000 to 150,000 lbs. per sq. in.; and plough steel from 190,000 to 350,000 lbs. per sq. in.

The strength of a wire rope is seldom more than 90 per cent of the strength of all of its wires in a testing machine; and the *average* strength is about 82½ per cent. This is due to the difficulty in making the rope straight at the ends of the test piece.

The length of wire rope, that is, the working load, is usually assumed to be the same as the breaking strength, for ordinary work. For severe or hazardous work the factor of safety is increased from 5 up to even 10 or 15, as for

drum and sheave should be large enough that the wires of the rope do not be strained beyond the elastic limit in passing over them. The diameters increase with the size of the rope and its speed. If the diameters are too small the life of the rope will be shortened.

As linseed oil, tar or other similar materials free from acids and other injurious substances, should be used freely and frequently in preventing wear, thus increasing the life of the rope. In order to protect the rope against the action of salt air, rust, etc., wire is often galvanized, as for ships' rigging, etc.; but ropes subject to constant use on drums and sheaves are not usually so treated.

A rope must not be coiled or uncoiled like hemp rope. When it is on a reel, the latter should be mounted upon a spindle or turn-buckle so that the rope can run off. When shipped in a coil it should be rolled like a wheel. All untwisting and kinking must be avoided. The rope is to be cut, soft iron wire should be served on each side of the division is to be made to prevent the rope from

The "circumferential" of a rope is the diameter of a circumscribing circle and the "axial" diameter.

5.—ROEBLING ROUND WIRE-ROPE.

(Swedish Iron, Cast Steel, Extra Strong Crucible Cast Steel, and Plough Steel.)

Note.—The above rope is furnished either galvanized or tinned; also with wire center—at an extra cost of 10 per cent for each. For standard hoisting rope the Swedish iron (A) and cast steel (B) with 19 wires to the strand, are used; while for transmission or haulage, the same, but with 7 wires to the strand, are used. Before ordering, consult the manufacturers in regard to the best size of rope, grade of steel, etc., to use, if not familiar with same.

EXCERPTS AND REFERENCES.

Telephone Cable in the St. Gotthard Tunnel ("Elektrotechn Zeitschrift" for June 27, 1901; Eng. News, Dec. 5, 1901).—Illustrated. A paper-and-air-insulated cable. It includes 7 two-wire circuits, each wire 1.8 m m. in dia., each set being covered with paper tape to a dia. of 7 m m.; stranded together and covered with a triple envelope of cotton and a double tin-lead sheath; outside is a layer of waterproof compound, a strong armor of interlocking steel wires and an outer coating of jute yarn soaked in a protecting compound. The finished external diameter is 44 m m., or 1.7 ins.

The above list is for pipe in standard lengths, with flanges attached or bolted joint connection.

We recommend the use of bolted joints with asphalted pipe for all high pressure water works.

RIVETED STEEL PIPE AS MANUFACTURED BY AMERICAN SPIRAL PIPE WORKS, CHICAGO.—Concluded.

Standard Flanges (Fig. 3) are used with spiral pipe unless otherwise specified. When other than the standard flanges are required, the outside diameter of flange, number and size of bolts, and diameter of holes may be made to face in any quarter, and holes straddle

Description.

Tests of lock-bar pipe 42" dia., Springfield, Mass.

Eng. Rec.

April 17, '09

37.—BRIDGES.

Economic Lengths of Spans.—If a bridge consisting of any number of spans (to be determined) is to be built over a stream or other crossing of length L , it can be shown that, aside from the (end) abutments,* the *most economic* layout of spans and piers will obtain when the cost of *each pier* is about equal to the cost of that portion of the structure which it supports when stripped of about *one-half* the floor system; that is, equal to the cost of the *supported trusses and laterals* and about *one-half* the floor, the cost *per lin. ft.* of same being assumed as proportional to *length of span*.

Let L = total length of crossing, in ft.;

P = cost in dollars of one pier at any given point of profile;

l = length of economic spans, in ft., based on P ;

x = number of spans l in the crossing L ;

C = cost in dollars per lin. ft. of trusses, laterals, etc., for span L ;

c = cost in dollars per lin. ft. of trusses, laterals, etc., for span l ;

y = total cost of trusses, laterals, etc., piers, and a proportionate cost of foundations in abutments.

Then, since $c = \frac{C}{x}$, and $l = \frac{L}{x}$

we have, $y = \frac{CL}{x} + Px$, (1)

Differentiating, and equating with zero, for minimum,

$$\frac{dy}{dx} = -\frac{CL}{x^2} + P = 0$$

whence, $P = \frac{CL}{x^2} = cl$ (2)

Now the value of c for span l may be obtained from any known value c' for span l' as follows:

$$c = \frac{c'l}{l'} \quad (3)$$

it being assumed of course that the same types of bridges are used and the same specifications; also that the lengths of spans l and l' do not vary greatly.

Equation (2) may be applied without serious error to a crossing with irregular profile as in Fig. 1. In such a case we would have, numbering the piers and spans consecutively,

$$P_1 = \frac{c_1 l_1 + c_2 l_2}{2}; P_2 = \frac{c_2 l_2 + c_3 l_3}{2}; P_3 = \frac{c_3 l_3 + c_4 l_4}{2}; \text{etc.}, \quad (4)$$

which is the proportion stated in the opening paragraph.

Fig. 1.

Referring to Fig. 1 and to equation (4) it will be noted that for the deeper, or rather more expensive, foundations the longer spans are required. The principles evolved above will apply to spans of plate girders, beams, etc., and also to many other economic problems.

* Abutments usually perform, in part, certain "constant" functions, as retaining walls, etc., not connected with "supporting" the spans, and, if included in the problem, these functions should be considered carefully.

Equation (2) may be transformed into

$$l = \frac{L}{x} = \sqrt{\frac{lP}{c}} = \sqrt{\frac{l}{w} \cdot \frac{P}{p}} \quad (5)$$

an economic form for general use, in which $\frac{l}{w}$ = ratio of length of span to weight in lbs. per lin. ft. of trusses, laterals, etc., and will be found to be fairly constant within quite wide limits of l ; and p = price in dollars per lb. of w .

Economic Depth of Plate Girders.—Equation (7) will usually give a greater depth of girder than practice warrants, but it will be useful in finding out how much material is sacrificed in any practical limitation of depth.

Let M = total max. bending moment in ft.-lbs. on girder;

A = area of top flange = area of bottom flange, in sq. ins.

f = allowable compressive stress in lbs. per sq. in. in top flange;

x = effective depth of girder = depth of web, in ins.;

t = thickness of web in ins.;

a = total horizontal section of vertical stiffeners and fillers, in sq. ins.;

L = length of span, in ft.;

y = total weight of girder, in lbs.

Then, for a steel girder, assuming no part of web to resist bending, we have,

$$\text{since } A = \frac{12M}{fx},$$

$$y = \frac{3.4 \times 24ML}{fx} + 3.4 Ltx + \frac{3.4}{12} ax. \quad (6)$$

Differentiating and equating with zero, for minimum,

$$\frac{dy}{dx} = -\frac{3.4 \times 24 ML}{fx^2} + 3.4 Lt + \frac{3.4}{12} a = 0,$$

$$\text{whence } x = 16.97 \sqrt{\frac{ML}{f(12Lt + a)}} \quad (7)$$

the economic depth of girder.

Ex.—A track stringer, 20-ft. span, is designed to support a total uniform load, including its own weight, of 2500 lbs. per lin. ft. Assuming $f = 10\,000$, $t = \frac{1}{2}$, and $a = 30$, find the economic depth.

Solution.—From equation (7) we have, since $M = \frac{2500 L^2}{8}$,

$$x = 16.97 \times 50 \times 20 \sqrt{\frac{20}{8 \times 10\,000 (240 \times \frac{1}{2} + 30)}} = 24\frac{1}{2} \text{ ins. Ans.}$$

Economic Depth of Trusses.—In the preceding case, of the plate girder, it is to be noted that the weight of each part of the girder is given in terms of the variable depth x in order that the value of x may be found for the minimum value of y . This will be done also in the present case, of the truss, but in order to introduce the working stresses per sq. in. in the compression members as "constants" into the fundamental formula (8) for total weight of truss it is convenient to assume that the bridge has been designed using a certain depth of truss (parallel chords) and find whether this depth is the most economic one, which will be the case when the value of x in equation (10) is equal to the assumed depth. If less, the depth will be decreased; if greater, increased. If the difference is slight the economic depth may be assumed equal to the value of x found. One or two trials will be sufficient in most cases. The general equation for total weight of steel truss members is

$$y = \begin{array}{cccccc} \text{Wt.} & & \text{Wt.} & & \text{Wt.} & & \text{Wt.} & & \text{Wt.} \\ \text{bottom} & & \text{top} & & \text{end} & & \text{vert.} & & \text{diag.} \\ \text{chord.} & & \text{chord.} & & \text{posts.} & & \text{susp.} & & \text{onals.} \\ B & + & T & + & E & + & P & + & V \end{array} \quad (8)$$

$$\begin{aligned} \text{In which } B &= 3.4 \Sigma \frac{M}{fx} (p + e) \\ T &= 3.4 p \Sigma \frac{M}{fx} (1 + \%) \\ E &= 3.4 \Sigma \frac{S(p^2 + x^2)}{fx} (1 + \%) \\ P &= 3.4 \Sigma \frac{Sx}{f} (1 + \%) \\ V &= 3.4 \Sigma \frac{Sx}{f} (1 + \%) \\ *D &= 3.4 \Sigma \frac{S(p^2 + x^2)}{fx} (1 + \%) \end{aligned}$$

Notation:

(May vary for each member.)

M = bending moment, ft.-lbs.;
 f = allowable stress per sq. in.;
 x = depth of truss, in ft.;
 p = panel length, in ft.;
 fe = added length for two heads;
 $\%$ = percentage added for details;
 S = vertical shear, in lbs.

Now, substituting the above values in equation (8) and using summated constants for simplicity, we have the following form:

$$y = 3.4 \left[\frac{B'}{x^2} + \frac{T'}{x} + \frac{E'p^2}{x} + E'x + P'x + V'x + \frac{D'p^2}{x} + D'x \right] \quad (9)$$

Differentiating and equating with zero, for minimum,

$$\frac{dy}{dx} = 3.4 \left[-\frac{B'}{x^3} - \frac{T'}{x^2} - \frac{E'p^2}{x^2} - \frac{D'p^2}{x^2} + E' + P' + V' + D' \right] = 0$$

$$\text{whence,} \quad x = \sqrt{\frac{B' + T' + E'p^2 + D'p^2}{E' + P' + V' + D'}} \quad (10)$$

In which $B' = \Sigma \frac{M}{f} (p + e)$, for each bottom chord member;

$$\begin{aligned} T' &= \Sigma \frac{Mp}{f} (1 + \%) & \text{" top " " } \\ E' &= \Sigma \frac{S}{f} (1 + \%), & \text{" end post; } \\ P' &= \Sigma \frac{S}{f} (1 + \%), & \text{" intermediate post; } \\ V' &= \Sigma \frac{S}{f} (1 + \%), & \text{" vertical suspender; } \\ D' &= \Sigma \frac{S}{f} (1 + \%), & \text{" diag. (incl. counters). } \end{aligned}$$

Estimating Weights of Bridges.—The correct weight of a proposed structure can be estimated only from a complete bill of material of the finished design, and young engineers should use this method on all possible occasions. After he has become expert in bridge designing he may resort to quicker methods, more or less approximate, depending on the purpose for which the estimate is to be used.

In designing a structure the live loads, snow load and wind loads must of course be known or assumed. The lengths of spans, if indefinite, may be fixed by the use of formulas (2) and (5); the depths of steel stringers, floorbeams and plate-girders, by equation (7); and the depth of trusses, by equation (10); bearing in mind, of course, that these values are often fixed arbitrarily and that any moderate variation from the economic depth will not add greatly to the weight or cost. For instance, the depth of plate-girders is usually assumed at about $\frac{1}{16}$ the span, and the depth of trusses at about $\frac{1}{4}$ to $\frac{1}{5}$ the span, the larger ratio applying to the shorter spans.

The steps in calculating the design and weights of an ordinary span are as follows: (1) That part of the roadway which directly supports the live load, as the paving, planking and street-car tracks of highway bridges; and the "track" (including rails, guard rails, ties and fastenings) of railroad (steam and electric) bridges, usually assumed at 400 to 450 lbs. per lin. ft. per track. (2) The ballast and corrugated flooring, if used. (3) The stringers or joists. (4) The floorbeams. (5) The top and bottom lateral systems. (6) The portal and vertical sway bracing. (7) The trusses.

* $(1 + \%)$ is used instead of $(p + e)$ to simplify equation (9).

† See formula (11) for value of e .

Each of the above operations, excepting (5) and (6), is dependent on the weights obtained from the preceding operations. Although no "backing up" is required we have to *assume* in some of the operations, as (3), (4) and (7), the weights of the members we are calculating, and sometimes two or three "assumptions" are necessary before the correct one is made.

In estimating the weights of details it is the practice with many engineers to add *certain percentages* to the weights of the *main ribs* of such members, or to add to their lengths, or both. The method of percentages is always uncertain, and may vary from a few %, for rivet heads, up to 50 or 60 % or more for latticing both sides of light channels. For instance, lacing may be used instead of latticing, or, what is still cheaper, occasional tie plates may be used. Again, a top chord may or may not have a cover plate, and with this uncertainty note what a variation in percentage for details this would imply. Very close estimates have been made on the *total weights of bridges* by adding a certain percentage, say 25%, to the weights of all the main members stripped of their details. As the percentage varies with the type of structure and the specification such a practice would be dangerous for any but the most careful expert.

A good formula for estimating the added length of eye bars to form the heads is the following: For forming two heads,

The added length in ft. $e = \frac{1}{4}$ diam of pin in ins. (11)
this to be added to length c . to c . of pins and estimated as a plain bar.

EXCERPTS AND REFERENCES.

Diagrams and Formulas for Weights of Steel Bridges and Trestles (By H. G. Tyrrell. Eng. News, May and June, 1901).—The following excerpts are noted from the formulas:

Unit stresses in all cases are 10,000 and 12,000 lbs. per sq. in. L = length of span in ft., c . to c . bearings.

Railway Bridges.—Weights are per lin. ft. of single track bridge for steel only; 1. 1., 2 100-ton engines followed by 4,000 lbs. per lin. ft. of track: Deck plate girder bridge, $100 + 9L$; deck lattice girder bridge, $100 + 8L$; half through pl. gird. br. with floor, $300 + 12L$; same with ties on shelf angle, $200 + 8\frac{1}{2}L$; same with trough floor, $600 + 10L$; riveted through truss br., $400 + 6L$; riveted deck truss bridge (ties on top chord), $200 + 7L$; pin through truss bridge, $400 + 5\frac{1}{2}L$; pin deck truss bridge with stringers, $400 + 6L$; pin deck truss bridge (ties on top chord), $300 + 6L$.

Railway Trestles.—Assumed loads same as above; weight of spans as above. Weight of bents and bracing is 9 lbs. per sq. ft. of side profile from ground to base of rail.

Electric Railway Bridges.—Live load assumed 25-ton cars, or 2,000 lbs. per lin. ft. of track: Beam bridges, $30 + 5\frac{1}{2}L$; deck plate girder bridges, $30 + 5L$; Pony truss bridges, $200 + 1.8L$; through truss bridges, $200 + 1.6L$.

Highway Bridges with Wooden Floors.—Assumed dead weight of floor is 40 lbs. per sq. ft.; assumed live load is 100 lbs. per sq. ft.; the weights are per sq. ft. of floor, and include that only with joists: Girder bridges and sidewalks, $3 + L + 4.4$; same without sidewalks, $3 + L + 3.4$; Truss bridges with sidewalks, $3 + L + 8$; same without sidewalks, $5 + L + 7$.

Highway Bridges with Solid Floors.—Assumed dead weight of floor is 150 lbs. per sq. ft.: Deck plate girder bridges, $3 + L + 2.6$; Half-through girder bridges, $3 + L + 2.4$; Truss bridges, $3 + L + 4$.

Graphical Method for Finding Bending Stresses in Eyebars (By W. E. Belcher. Eng. News, July 17, 1902).—From the formula,

$$P = \frac{4\,900\,000\,h}{P_1 + 23\,333\,000 \frac{h^2}{l^2}}$$

Where P = stress in lbs. per sq. in. due to bending;

P_1 = working tensile stress in lbs. per sq. in.;

h = depth of bar in inches;

l = length of bar in inches.

The formula is based on the value of $E = 28\,000\,000$ and a weight of metal of 0.28 lb. per cu. in.

38.—RAILROAD BRIDGES.

I.—MOMENTS AND SHEARS—BEAMS OR GIRDERS.

(a) Uniformly Distributed Loads.

w = load in lbs. per lin. foot; l = span in feet.

FULL LOADING—MOMENTS AND SHEARS—FIGS. 1 AND 2.

At any point distant x from left end:

$$\text{Moment } M_x = \frac{1}{2} wx, (l-x), \text{ in ft.-lbs.}$$

$$= \frac{6}{8} wx (l-x), \text{ in in.-lbs.}$$

Maximum moment (at center),

$$= \frac{1}{8} w l^2, \text{ in ft.-lbs.}$$

$$= \frac{1}{8} w l^2, \text{ in in.-lbs.}$$

Fig. 1. Moments.

Fig. 2. Shears.

$$\text{Shear } S_x = w \left(\frac{l}{2} - x \right) \text{ in lbs.,}$$

(left end positive; right end negative).

Maximum shear (at ends),

$$= \frac{1}{2} w l, \text{ in lbs.}$$

Minimum shear (at center) = 0.

Note that maximum moment occurs at point of minimum shear; and minimum moment occurs at point of maximum shear.

To Draw a Moment Parabola, divide the span into *any number* of equal parts, odd or even; number the points from one end, beginning with zero; and for ordinates, multiply together the numbers equidistant from center. Afterward, all ordinates so obtained may be multiplied by a constant (one that will give the required middle ordinate). See Figs. 3 and 4

Fig. 3. Even.

Fig. 4. Odd.

PARTIAL LOADING—MOMENTS AND SHEARS—FIGS. 5 AND 6.

At any point distant x ($> a$) from left end:

$$\text{Moment } M_x = \frac{w}{2} \left[\frac{x}{l} (l-a)^2 - (x-a)^2 \right], \text{ in ft.-lbs.}$$

$$= \frac{6}{8} w \left[\frac{x}{l} (l-a)^2 - (x-a)^2 \right], \text{ in in.-lbs.}$$

Maximum moment is at $x = \frac{l^2 + a^2}{2l}$.

Fig. 5. Moments.

Fig. 6. Shears.

curve of moments directly above the loading, to the right of T , and to the left of T it is a tangent to the parabola. The point I is directly over the center of gravity of the load, and the

$$\text{i.e., when } x=a, \text{ is } M_a = \frac{wa}{2l}(l-a)^2, \text{ in ft.-lbs.} \\ = \frac{6wa}{l}(l-a)^2, \text{ in in.-lbs.}$$

$$\text{ar } S_x = \frac{w}{2l}(l-a)^2 - w(x-a), \text{ in lbs.} \\ (\text{left end positive; right end negative}).$$

imum (+) shear (at $x=a$):

$$= \frac{w}{2l}(l-a)^2, \text{ in lbs.}$$

imum (-) shear (at $x=l$):

$$= -\frac{w}{2l}(l-a)^2 - w(l-a), \text{ in lbs.}$$

$$\text{imum (0) shear is at } x = \frac{(l-a)^2}{2l} + a = \frac{l^2 + a^2}{2l}.$$

maximum moment occurs at point of minimum shear; and
minimum moment occurs at point of maximum shear.

ED LOADING—MOMENTS AND SHEARS—FIGS. 7 AND 8.

istant x ($>a$ and $<l-c$) from left end:

$$\text{ment } M_x = \frac{wx}{l} \left(\frac{b^2}{2} + bc \right) - \frac{w}{2}(x-a)^2, \text{ in ft.-lbs.} \\ = \frac{12wx}{l} \left(\frac{b^2}{2} + bc \right) - 6w(x-a)^2, \text{ in in.-lbs.}$$

$$\text{ment } M_a \text{ (when } x=a), \text{ at } T_1 \\ = \frac{wa}{l} \left(\frac{b^2}{2} + bc \right) \text{ ft.-lbs.} = \frac{12wa}{l} \left(\frac{b^2}{2} + bc \right) \text{ in.-lbs.}$$

$$\text{ment } M_{a+b} \text{ (when } x=a+b), \text{ at } T_2 \\ = \frac{wc}{l} \left(\frac{b^2}{2} + ab \right) \text{ ft.-lbs.} = \frac{12wc}{l} \left(\frac{b^2}{2} + ab \right) \text{ in.-lbs.}$$

$$\text{imum moment is at } x = \frac{b}{l} \left(\frac{b}{2} + c \right) + a.$$

Isolated Loading

Fig. 8. Shears.

Fig. 7. Moments.

$$\text{ear } S_x = \frac{w}{l} \left(\frac{b^2}{2} + bc \right) - w(x-a), \text{ in ft.-lbs.} \\ = \frac{12w}{l} \left(\frac{b^2}{2} + bc \right) - 12w(x-a), \text{ in in.-lbs.}$$

imum (+) shear (at $x=a$)

$$= \frac{w}{l} \left(\frac{b^2}{2} + bc \right) \text{ ft.-lbs.} = \frac{12w}{l} \left(\frac{b^2}{2} + bc \right) \text{ in.-lbs.}$$

imum (-) shear (at $x=a+b$)

$$= -\frac{w}{l} \left(\frac{b^2}{2} + ab \right) \text{ ft.-lbs.} = -\frac{12w}{l} \left(\frac{b^2}{2} + ab \right) \text{ in.-lbs.}$$

$$\text{imum (0) shear is at } x = \frac{b}{l} \left(\frac{b}{2} + c \right) + a.$$

extension of the principle, the remarks under "Partial loading" apply to "Isolated loading." Thus, in the above Fig. (7)

the "curve of moments" comprises the parabola T_1-T_2 and the adjacent tangents, their intersection at I being vertically above the center of gravity of the uniform load.

(b) **Concentrated (Engine, Car, Axle, Wheel, etc.) Loads.**—During the past 75 years the weight of the locomotive has increased from about 7 to over 200 tons. In approaching the latter mark many engineers predicted that we were reaching the limit, but similar prophecies may be recalled for the 100-ton engine which appeared and disappeared as a standard for bridge calculations during the short period of about ten years. The following may be considered as typical for our heaviest loading—present and prospective—for bridge calculations:

Two engines coupled and followed by uniform load of w pounds per lin. ft.

Axle concentrations: Bogie axle load = $5w$ 1 axle.
 Driving " " = $10w$, each; 4, spaced 5 ft.
 Tender " " = 6 to $7w$ " ; 4, spaced 5 and 6 ft.

Or, for floor loads, { Driving } " " = $14w$ " ; 2, spaced 7 ft.
 { or Car }

as per the following diagrams:

Type R—Engine Diagrams—Axle Loads.

Note.—Wheel* or rail loads w_1 are one-half of axle or track loads w .)

Figs. 9.

* By substituting w_1 for w the diagrams will represent "wheel-load" instead of "axle-load" diagrams. Wheel load diagrams are often used in calculations, but axle load diagrams are safer. Digitized by Google

TYPICAL MOMENT DIAGRAM—"R 50" LOADING.

Moment Diagram of special type "R 50" locomotive (172.5 yd. long) by 5000 lbs. per lineal foot per track. The loads are given in thousands of pounds per "axle" and per "track" in order that the diagram be convenient for calculation of one truss for double track bridges in all cases. For practical bridge calculations it will be convenient to reproduce this diagram on tracing cloth to a scale of say 1" = 10 ft. and use skeleton diagrams of bridges drawn to the same scale. By placing the engine diagram over the span the moments may be obtained for any position and hence the maximum moment obtained in the span.

Diagrams in Table 1 are proportional throughout it is necessary to multiply the results obtained from the use of the diagram, by the factors 0.9, 1.1, 1.2, respectively.

Table 2, following, shows the positions of axle loads, R 50,* giving maximum bending moments on spans up to 55 feet; the maximum bending moments in ft.-lbs. from these positions; and the maximum shears. Useful in the design of girders, stringers, and floorbeams.

2.—BENDING MOMENTS AND SHEARS FOR "R 50" LOADING.

II.—MOMENTS AND SHEARS—SPANS WITH FLOOR BEAMS.

(a) **Uniformly Distributed Loads.**—The maximum moment at any panel point obtains with the span fully loaded from end to end. The maximum shear in any panel obtains with the head of the moving load at or in that panel; specifically, when the length of moving load in the panel + panel length = (the number of the panel from the right end of span, minus 1) + (total number of panels in the span, minus 1). Thus:

Let p = panel length in feet,

n = total number of panels in span,

x = the number of the panel from right end of span; then for maximum shear in panel x , the length of load in "panel x " = $p \frac{x-1}{n-1}$. Thus for

a six-panel span the head of load for maximum shear in the 5th panel is $\frac{x-1}{n-1} = \frac{5-1}{6-1} = \frac{4}{5}$ across the panel; for the 4th

panel, $\frac{3}{5}$; for the 3rd panel, $\frac{2}{5}$; etc. The maximum shear in the 6th panel obtains with the full panel (and bridge) loaded.

Fig. 11.

In practice, however, the above refinement is eliminated, the panel loads being considered as concentrated at the panel points or joints—upper for "deck" and lower for "through" bridges. This applies also to dead loads, for short spans. For long, through spans a certain portion, say $\frac{1}{2}$ to $\frac{1}{3}$, of the dead load per panel is often assumed to be carried at the top chord joints.

In calculating live load stresses, engineers as a rule prefer to use specified engine diagrams, somewhat heavier and more severe, for the structure, than the actual engines in use or immediately contemplated. This is by far the safer, more scientific and more economical when we consider the strength of a structure to be measured by its weakest part. An approximation to actual engine diagrams is the use of equivalent uniform loads which may be used with or without "engine excess."

(b) **Concentrated Loads—Maximum Floor-Beam Reactions.**—The loading which gives the greatest bending moment at the *center* of a span *two panels* in length, will give also the greatest loading at *that point* when supported by a floor-beam, and this loading or its equivalent is called the floor-beam reaction—a necessary factor in the design of the floor-beam itself.

Table No. 3 gives the floor-beam reactions due to "R 50" axle loads, and the positions of the loads, over two panel lengths, which produce these reactions. For any other loading of Type R the floor-beam reaction will be directly proportional to the weights on the drivers.

3.—MAXIMUM FLOORBEAM REACTIONS AND POSITIONS OF LOADING FOR SAME. TYPE "R 50."

(c) **Concentrated Loads—Positions for Maximum Moment.**—In order to find the stresses in the top and bottom chords of bridge trusses and girders with floor-beams, it is necessary to know the maximum bending moments at the floor-beam or panel points. The main problem consists in finding the "position" of the loading at each panel point, the bending moment being then found by taking moments about that point. The chord stresses are obtained by dividing the bending moments in ft.-lbs. by the respective moment arms of the chord pieces, in feet. For trusses with parallel chords the moment arm is constant, being the height of truss.

The position of loading for maximum bending moment at any panel point* usually obtains:

- (1) When the heaviest loads are *nearest* the point.
- (2) When one of these loads is *at* the point.
- (3) When the average loading per lineal foot to the left of the point = the average loading per lineal foot on the whole span (the load *at* the point to be applied in whole or in part to either portion of the span).

Chord Stresses in Pratt Truss.

Problem.—Find the live-load stresses in the top chord member T and in the bottom chord member B of Pratt† truss, Fig. 12, of a single track railroad bridge, 144 ft. span; using loading "R 50" (page 691). Note that in *all cases* the moving load comes on at the right hand end of span.

Fig. 12.

Solution.—By "cutting" sections $a-a$ and $b-b$ it is evident that the bending moment for maximum stress in T will be at the point P' , and for B , at the point P , directly above. Hence the same bending moment will do for both stresses. Applying the moment diagram and the rules just given, we place one of the heavy loads at P' so that the loads to the left of P' will equal $\frac{1}{2}$ (or $\frac{1}{4}$) the total loads on the bridge. Hence, if load (5) is placed at P' the load to the left is 175 to 225 thousand lbs., while the whole load on the span is $690 + 5 \times 22 = 800$ thousand lbs. As $\frac{1}{2}$ of 800, or 200, is between 175 and 225 we adopt this position as the *probable* one for maximum moment at P' . By trial we find this to be true and that the moment at $P' = 12,045,000$ ft.-lbs. As there are two trusses each resisting one-half the moment, and further, as the moment arms are 26 ft. the stresses in T and B are each equal to $12,045,000 + 52 = 231,600$ lbs.—compression in T and tension in B . If the engine loading is "R 40" instead of "R 50" the stresses will be $\frac{4}{5}$ the above or 185,300 lbs., etc.

The following are methods of calculation with various loads at P' , using the engine diagram:

Load (3) at P' .	Load (4) at P' .	Load (5) at P' .
12 ft. of uniform load.	17 ft. of uniform load.	22 ft. of uniform load.
Mom. at $H = 40,090$.	Mom. at $H = 40,090$.	Mom. at $H = 40,090$.
Add $690 \times 12 = 8,280$.	Add $690 \times 17 = 11,730$.	Add $690 \times 22 = 15,180$.
" $5 \times 12 \times 6 = 360$.	" $5 \times 17 \times 8\frac{1}{2} = 722.5$.	" $5 \times 22 \times 11 = 1,210$.
48,730.	52,542.5	56,480.
$\frac{48,730 \times 36}{144} = 12,182.5$	$\times \frac{36}{144} = 13,135.6$	$\times \frac{1}{4} = 14,120$.
Deduct 575.	1,200.	2,075.
11,607.5	11,935.6	Max. = 12,045.

Hence the maximum moment is 12,045,000 ft.-lbs., as above noted. With load 6 at P' the moment is only 11,870,600 ft.-lbs.

* The moment at any floor-beam panel point for any system of loading is the same as if there were no floor-beams.

† In this case the chord stresses will be the same whether the bridge is "deck" or "through."

Chord Stresses in Warren Truss.

Triangular Web System.—For practical reasons the Post truss and the through triangular or Warren truss types have nearly disappeared. The Warren truss remains principally for deck spans and swing bridges; and for short, fixed, through spans. For deck spans it is economical to erect verticals at the lower chord panel joints to support intermediate floor-beams as in Fig. 13.

Fig. 13.

Using the same live load, "R 50," as in the preceding case, note that the stress in the top chord members *TT* is equal to the stress in *T* of the Pratt truss, Fig. 12, namely, 231,600 lbs. It is obtained by placing load (6) of the engine diagram at *t*, a floor-beam point, and taking moments about *t*.*

Consider, now, the stress in the upper chord *ab*, Fig. 13, assuming no floor-beam at *t*, in a vertical line with the center of moments, *t*. For this case the loading for maximum will be somewhat modified, and the following rule will usually apply: *The average loading per lineal foot to the left of the center of moments, t, (including one-half† the load in the panel under consideration, ab) = the average loading per lineal foot on the whole span.* After the position of loading for maximum has been fixed take moments about *t*, using the reaction at *a* due to loading in panel *ab*, in deducting the negative moment.

(d) **Concentrated Loads—Positions for Maximum Shear.**—On page 693, under uniformly distributed loads, we find that for maximum shear in any panel the length of the moving load in that panel will be $p \frac{x-1}{n-1}$, in which *p* = panel length, *x* = number of the panel from right hand end of span, and *n* = the total number of panels. Thus, the head of the moving load† in any panel is such that *the average load per lineal foot in the panel equals the average load per lineal foot on the whole span.* This principle may be applied tentatively in fixing the position of concentrated loads for maximum shear.

The position of loading for maximum shear in any panel of a truss with simple web system|| usually obtains:

- (1) When the heaviest loads are nearest to and just to the right of the panel.
- (2) When one of these loads is at the panel point at the right hand end of the panel in question.
- (3) When the average loading per lineal foot in the panel = the average loading per lineal foot on the whole span (the load at the panel point at the right hand end of the panel may be applied in whole or in part to the panel loading).

Problem.—Find the live-load shear in panel *t b*, Fig. 13, of a two-truss double track deck railroad bridge, 144 ft. span; using loading "R 50."

* The stress in *B* of the Warren truss is greater than *B* of the Pratt, and is obtained by taking moments about *b*, as would naturally be indicated by the cutting section *c-c*, with load (8) at the panel point. This produces a moment of 14,698,750 ft.-lbs. and a corresponding stress in *B*, for one triangular truss, of 282,670 lbs., equivalent to stress in *B'* of the Pratt truss.

† Accurately, at *a* + *ab*, whether it is one-half or any other fraction.

‡ The head of the moving load for maximum shear is at the "neutral shear point" because any concentrated load at that point produces zero shear in the panel. A load to the right of the neutral point will produce positive shear, while a load to the left will produce negative shear.

|| For special case with sub-panel system, see Sec. 40, Highway Bridges, page 724.

Solution.—The three conditions above named for maximum shear are fulfilled by placing load (3) at *b*, whence the total load in the panel, 75 to 125, equals the total load on the bridge, 660, divided by the number of panels, 8; thus, $660 \div 8 = 82.5$. Inspection, however, reveals to us the possibility of a maximum with load (2) at *b*, hence we solve for these two positions, using moment diagram:

$$R_1 l = \begin{array}{r} \text{Load (2) at } b. \\ 29,560 \\ + 630 \times 5 = 3,150 \\ \hline 32,710 \end{array}$$

$$\begin{array}{r} \text{Dividing by } l, R_1 = 227,153 \text{ lbs.} \\ \text{Deduct reac-} \\ \text{tion at } i \text{ due to} \\ \text{load (1) in pan-} \\ \text{el, } 25 \times \frac{9}{18} \end{array} \left. \vphantom{\begin{array}{r} 227,153 \\ 227,153 \\ 227,153 \\ 227,153 \\ 227,153 \end{array}} \right\} = 11,111 "$$

$$\text{Shear} = 216,042 "$$

$$R_1 l = \begin{array}{r} \text{Load (3) at } b. \\ 33,340 \\ + 660 \times 4 = 2,640 \\ \hline 35,980 \end{array}$$

$$\begin{array}{r} \text{Dividing by } l, R_1 = 249,861 \text{ lbs.} \\ \text{Deduct reac-} \\ \text{tion at } i \text{ due to} \\ \text{loads (1) and} \\ \text{(2) in panel} \end{array} \left. \vphantom{\begin{array}{r} 249,861 \\ 249,861 \\ 249,861 \\ 249,861 \\ 249,861 \end{array}} \right\} = 31,944 "$$

$$\text{Shear} = 217,917 "$$

Therefore, maximum shear, 217,917 lbs., is obtained with load (3) at *b*. With load (4) at *b* the shear is 206,944 lbs. The compressive stress in the diagonal

$$r_b \text{ is } 217,917 \times \frac{i'b}{r'i} = 217,917 \times 1.216 = 264,990 \text{ lbs.}$$

III.—LATERAL BRACING.—WIND AND CURVE PRESSURE.

Horizontal or lateral bracing is designed to resist the lateral forces due to wind pressure, and the centrifugal pressure of moving trains on curves; to shorten the unsupported "column length" of upper chord, for economy of design; and to give general rigidity to the structure. Stiff bracing is preferable to rods.

Wind Pressure.—The direct wind pressure on any exposed surface is about proportional to the square of the velocity.* A velocity of 100 miles per hour produces a normal pressure of about 50 lbs. per sq. ft.; 90 miles per hour, about 40 lbs.; and 80 miles per hour, about 30 lbs. As rigidity is a very essential feature it is advisable to use the higher figure, 50 lbs., as the pressure per sq. ft. on the exposed surface of all trusses and the floor system when the bridge is unloaded. An *alternative* wind load of 30 lbs. per sq. ft. on the same surface and also on a moving train between elevations 2.5 and 10 ft. above base of rail is also prescribed. Sometimes the wind load per lin. ft. is stated in actual amounts for each chord. Thus, a load (either fixed or moving) of say 150 lbs. per lin. ft. for the unloaded chord and a moving load or say 600 lbs. per lin. ft. for the loaded chord. See Wind Pressure under General Specifications for Steel Railroad Bridges, following.

Problem.—Find the stresses in top lateral system of single track through Pratt truss span of 144 ft., as per following sketch; loading 75 lbs. per lineal foot for each chord ($18 \times 75 = 1,350$ lbs. per joint.)

Fig. 14.

Solution.—Let the diagonals and struts be stiff members and let either single member in each panel be capable of "taking" all the shear, in tension or compression. Then with a moving load from A to B of 1350 lbs. per single joint or 2700 lbs. per double joint (both chords) the shears in panels *a*, *b* and *c*, due to the top lateral span of 108 ft., are 6750 lbs., 4500 lbs. and 2700 lbs., respectively. Hence the stresses in the diagonals ($\frac{1}{2} \times$ the

* Pressure in lbs. per sq. ft. = $\frac{(\text{Velocity in miles per hour})^2}{250}$, approximately. (Recent experiments by M. Eiffel, and also by Dr. Stanton, indicate that for velocities of 40 to 90 miles per hour the denominator of the fraction may safely be increased from 250 to 300 or 333.—See *Engineering Digest*, March, 1908.) See also, Section 46, Roofs, pages 794, etc.

shears) are 10,100 lbs., 6,800 lbs. and 4,100 lbs. In practice, minimum sections of material are specified, either direct or by formula, below which the design would be considered weak no matter how small the stresses.*

IV.—PORTAL AND INTERMEDIATE VERTICAL BRACING.

Portals should be designed to transmit all lateral-bracing stresses at the unloaded or far chords, directly to the abutments through the end posts. For long spans, vertical bracing is inserted at the intermediate posts rather for stiffness than to transmit any wind pressure from one lateral bracing system to another, although it is usually designed sufficiently strong to meet the "local" wind pressure. The same principles which apply to portal- also apply to intermediate bracing, hence our remarks will be confined to the former, and for brevity of explanation, to "through" bridges.

The calculations of portal stresses are much simplified by making certain assumptions which render the framework quite statically determinate. These assumptions are that the bottoms of the end posts are hinged laterally; that all stiff-riveted portal connections are also hinged; and that for a double or multiple system of portal bracing only one simple statically determinate system acts at a time. These assumptions are on the side of safety.

The following simple illustrations are typical. They are tipped to a horizontal position so that the acting forces P may be vertical and perhaps better illustrate the cantilever principle. Note that the horizontal and vertical reactions at the *bottom* of the two end posts are numerically the same for each post and, consequently, the shears and the bending moments in the latter are respectively similar.†

Diagonal d in tension.

Fig. 15.

Diagonal d in compression.

Fig. 16.

Fig. 15 or 16, with either P or P' acting: $H = H' = \frac{P}{2}$ or $\frac{P'}{2}$; $V = V' = \frac{Pl}{w}$ or $\frac{P'l}{w}$; stress in $x = +\frac{Pl}{w}$ or $+\frac{P'l}{w}$; stress in $x' = -\frac{Pl}{w}$ or $-\frac{P'l}{w}$;

Fig. 15, with either P or P' acting: Fig. 16, with either P or P' acting:
Stress in $b = -\frac{Pl}{2y}$ or $-\frac{P'l}{2y}$. Stress in $b = +\frac{Pl}{2y}$ or $+\frac{P'l}{2y}$.

" " $t = -\left(P + \frac{Px}{2y}\right)$ or $-\frac{P'x}{2y}$. " " $t = +\frac{Px}{2y}$ or $+\left(P' + \frac{P'x}{2y}\right)$.

" " $d = +\frac{Pl}{y} \cdot \frac{d}{w}$ or $+\frac{P'l}{y} \cdot \frac{d}{w}$. " " $d = -\frac{Pl}{y} \cdot \frac{d}{w}$ or $-\frac{P'l}{y} \cdot \frac{d}{w}$.

The following are some of the usual types of portals.

Figs. 17.

* For highway bridges adjustable rods are often used instead of stiff members and it is customary to specify an initial stress of, say, 10,000 lbs. to be added to the calculated stress in proportioning the dimensions of the laterals.

† In the design of the posts these wind stresses have to be "considered" in addition to the regular stresses as truss members.

Fig. *a* is the simplest and the one just analyzed by calculation. By similar methods and with reasonable assumptions the others may be calculated readily.

V.—GENERAL SPECIFICATIONS FOR STEEL RAILROAD BRIDGES.

The main specifications below are adapted from those of the American Bridge Company (Am. Br. Co.), 1900, C. C. Schneider, Vice President. The foot-notes are inserted by the writer as showing the practice (in deviation or otherwise) of a few of our leading railroad companies, as follows: Chicago, R. I. and Pacific (*C. R. I. & P.*), 1906; J. B. Berry, Chief Engineer. Del., Lack. and Western (*D. L. & W.*), 1903; A. E. Deal, Bridge Engineer. Lake Shore and Mich. Sou. (*L. S. & M. S.*), 1904; Sam'l Rockwell, Chief Eng. * Lehigh Valley (*L. V.*), 1906; Walter G. Berg, Chief Engineer. Philadelphia and Reading (*P. & R.*), 1906; William Hunter, Chief Engineer. Southern Pacific (*S. P.*), 1906; William Hood, Chief Engineer.

(a.) General Description.

Material.—1. To be of rolled steel† as specified below. †Cast iron or cast steel permitted only in machinery of movable bridges and in special cases for shoes and bearings.

Types of Bridges Recommended.—2. Limiting spans, in ft. to be: ||

Clearance.—3. On straight line a clear section shall be provided to conform to given requirements.‡ The width must be increased so as to allow the same minimum clearance on curves§ and on double track.

* "All Railroad Bridges on the Lehigh Valley Railroad System are to be built in accordance with the 'General Specifications for Steel Railroad Bridges and Viaducts; New and Revised Edition, 1901; by Theodore Cooper, Consulting Engineer,' modified as follows:" [Some of the modifications are incorporated in these foot-notes.]—F. E. Schall, Bridge Engineer.

† *P. & R.* allows use of wrought iron for laterals and unimportant members.

‡ *L. S. & M. S.* specifies all castings to be cast steel. *S. P.* specifies rollers for swing bridges to be cast steel; expansion rollers to be bar steel, or cast steel of equal strength.

H' = to Top of Rail.

H = to Base of Rail.

§ Increase width for curvature and super-elevation for car 80' lg., 14' high and 60' c-c. trucks—*C. R. I. & P.* Increase *m* 1 in. per deg. of curvature, and increase *m* on inside of curve 2½ ins. additional per each inch super-elevation of track. Width to be increased proportionately for 2 or more tracks.—*L. S. & M. S.*

Spacing of Trusses.—4. Width between centers of trusses to be not less than $\frac{1}{4}$ * of the span.

Spacing of Deck Plate Girders.—5. Generally 6 $\frac{1}{2}$ ft. centers.

Floor Beams.—6. Shall be riveted between the posts, above or below the pin, in through bridges.

Spacing of Stringers.—7. Generally 6 $\frac{1}{2}$ ft. centers, the tracks being 13 ft. centers, standard.

Wooden Floor.—8. Cross-ties 8"x8" for stringers spaced 6 $\frac{1}{2}$ ft. centers. For spacing over 6 $\frac{1}{2}$ ft., ties to be proportional for fiber strain not to exceed 1000 lbs. per sq. in. on timber, assuming max. wheel load distributed over three ties. Ties to be spaced 6" or less in the clear, notched down $\frac{1}{4}$ ", and have full bearing on stringers. 9. Every fifth tie to be fastened to stringer by a $\frac{1}{2}$ " bolt.

Guard Rails.—10. Timbers 6"x8" on each side of each track, with inner faces not less than 3'-3" from cen. of track. To be notched 1" over every tie and fastened to every third tie and at each splice by a $\frac{1}{2}$ -in. bolt. Splices to be over floor timbers, with half-lap joints 6' long. 11. Floor timbers and guards to be continuous over piers and abutments. 12. On curves, outer rails to be elevated as may be required.

(b) Loads.

Dead Load.—13. In estimating the weight of the structure for the purpose or calculating stresses, timber is assumed at 4 $\frac{1}{2}$ lbs. per ft. B.M.; and rails, spikes and joints at 100 lbs. per lin. ft. of track.

Live Load.—14. A moving load for each track, consisting of two engines coupled at the head of a uniformly distributed train load, placed so as to give the greatest stress in each part of the structure. The load will be as specified by the railroad company. Cooper's standard loading, however, is recommended. (See Tables 4 and 5, pages 707, 708.)

* And preferably not less than $\frac{1}{4}$ of the span.—*L. S. & M. S.*

† 7 ft. for spans up to 60 ft.; 8 ft. for spans 60 to 110 ft.—*C. R. I. & P.*

‡ 7 ft.—*C. R. I. & P.* and *S. P.* 6 ft. for double track through, and deck plate; 8 ft. for single track through.—*P. & R.* 6 $\frac{1}{2}$ ft.—*D. L. & W.* and *L. S. & M. S.*

§ 8"x8" by 10 ft., framed to 7 $\frac{1}{2}$ ", for stringers spaced 6 $\frac{1}{2}$ ft. centers; depth of tie to be increased 1" per each 6" increase in stringer spacing. Ties spaced 12" centers, every fourth tie fastened to each stringer by a $\frac{1}{2}$ " hook bolt.—*L. S. & M. S.* Ties (yellow pine or white oak) to be proportioned to an extreme fibre stress of 800 lbs. per sq. in. from the loading; spaced not over 6" in clear, notched down $\frac{1}{4}$ ", and secured to supporting girders by $\frac{1}{2}$ " bolts not over 6 ft. apart.—*L. V.*

° Guards to be 8" wide and 6" deep, framed to 4" over ties, with inner edges 4'-2" from cen. of track. They shall be fastened to the ties by a $\frac{1}{2}$ " bolt through every fourth tie, these bolts to be through the ties which are connected to the stringers by hook bolts.—*L. S. & M. S.* Guards to be 6"x8" southern yellow pine, notched 1 $\frac{1}{2}$ " over every tie, bolted by a $\frac{1}{2}$ " bolt to every third tie and spliced over a tie by half and half joint 8" wide, bolted at splice; the inner face of guard to be 4'-1 $\frac{1}{2}$ " from cen. of track; and all heads or nuts on upper faces of guard timber to be countersunk below surface of wood.—*L. V.*

¶ Timber at 4 $\frac{1}{2}$ lbs. per ft. B. M.; ballast, 100 lbs. per cu. ft.; rails and fastenings, 150 lbs. per lin. ft. of track.—*C. R. I. & P.* The floor, consisting of the ties, rails, guard rails, and all spikes and bolts necessary to fasten same, assumed at 400 lbs. per lin. ft. of track.—*D. L. & W.* Ordinary floor at 400 lbs. per lin. ft. of track. Make due allowance when plank- or ballast floor is used.—*L. S. & M. S.* Ordinary floor assumed at 500 lbs. per lin. ft. of track. For ballast floors allow following weight per cu. ft.: Ballast, 120 lbs., Concrete, 140 lbs., Asphalt, 90 lbs., Lumber 54 lbs.—*P. & R.* Ordinary floor assumed at 500 lbs. per lin. ft. per track. Apply three-fourths of total dead load at panel points of loaded chord, and one-fourth at unloaded chord.—*S. P.*

¶ The following are Railroad Co. Standards. Diagrams 1 and 2 are shown, and that one which will produce the greatest stress in any member

Impact.*—15. The effect of impact and vibration due to live load determined by the following formula and added to the live

$$I = S \left(\frac{300}{L + 300} \right) \quad (\text{See Table 6, page 709.})$$

to be added to live load stresses S .

with in ft. of loaded track distance which produces the maximum member.

the latter usually for stringers and floor beams. Loads (lbs.) and uniform loads, per lin. ft. of track.

e direction):

Two 192½ ton consolidated engines:

$$\left. \begin{array}{l} \text{ed} \\ \text{ck} \end{array} \right\} I = S \left(\frac{300}{L + 300} + \frac{100 - L}{500} \right); \text{ Over } \left. \begin{array}{l} \text{ } \\ \text{ } \end{array} \right\} I = S \frac{300}{L + 300} \quad \begin{array}{l} \text{---C.R.} \\ \text{I. \& P.} \end{array}$$

bridges and other movable structures while in motion only. For counter stresses, $I = L$. For hip and panel suspenders connections of the floor system, $I = 1.25 L$. For all other

$\frac{L}{D}$. In which L = combined stresses from live load and cen- and D = dead load stress.—L. S. & M. S.

Wind Pressure.*—16. Shall be assumed acting in either direction horizontally: *First*. At 30 lbs. per sq. ft. on exposed surface of all trusses and the floor as seen in elevation, in addition to a train of 10 ft. average height, beginning 2'-6" above base of rail, moving across the bridge. *Second*. At 50 lbs. per square foot on the exposed surface of all trusses and the floor system. The greatest result to be assumed in proportioning the parts. 17. For determining the requisite anchorage for the loaded structure, the train shall be assumed to weigh 800 lbs. per lin. ft.

Momentum of Train.—18. Coefficient of aliding friction of wheels on rails, in stopping train, to be assumed at 0.2; this to apply to longitudinal bracing of trestle towers and similar structures.

Centrifugal Force of Train.—19. On curves, assume the centrifugal force C , in lbs., due to each train, to be: $C = 0.03$ (Wt. of train in lbs. $\times$ degree of curvature. up to 5°); the coefficient (0.03) to be reduced 0.001 for every degree of curvature above 5 degrees.

(c.)—Proportion of Parts.

Least Thickness of Material.†—20. Except for lining or filling vacant spaces, $\frac{1}{4}$ " thick for main members and their connections, and $\frac{1}{8}$ " thick for laterals and their connections.

Permissible Tensile Stresses.‡—21. On all parts of structure, sum of maximum loads, together with impact: Soft steel, 15000; Medium steel, 17000 lbs. per sq. in. 22. Same limiting stresses for wind pressure, centrifugal force, or momentum of train. 23. For net section, deduct size of rivet hole $\frac{1}{4}$ " larger than diam. of rivet. 24. For pin connected riveted

* "Lateral Load:" 750 lbs. per ft. of loaded chord; 200, for unloaded; both considered as moving. "Wind load" on viaduct towers: 50 lbs. per sq. ft. on $1\frac{1}{2}$ times the vertical projection of structure unloaded; or 30 lbs. per sq. ft. on same surface plus 400 lbs. per lin. ft. of structure applied 7 ft. above the rail for assumed wind on train when the structure is either fully loaded or loaded on either track with empty cars assumed to weigh 1200 lbs. per lin. ft., whichever gives the greater stress.—*C. R. I. & P.*

For spans, 300 lbs. per lin. ft. of bridge, acting on moving train of loaded or unloaded cars, for lateral system attached to the loaded chord, and 300 lbs. per lin. ft. acting on trusses and divided equally between top and bottom lateral systems. Trestle towers shall be proportioned for above wind forces for spans, and in addition thereto a wind pressure of 100 lbs. per vertical ft. of tower.—*D. L. & W.*

For single track bridges, 300 lbs. live load and 150 lbs. dead load per lin. ft. of loaded chord, and 150 lbs. dead load per lin. ft. of unloaded chord. For double track bridges, increase the above loads 50%. Where 30 lbs. per sq. ft. of exposed surface produces larger dead loads than the above in plate girder bridges or special structures, these shall be taken instead.—*L. S. & M. S.*

For girder bridges, 200 lbs. per lin. ft. for each chord. Also, for loaded chord, a moving load of 400 lbs. per lin. ft., with point of application $7\frac{1}{2}$ ft. above the rail. For viaducts and trestle towers, 50 lbs. per sq. ft. of the projected surface of two trusses and two sides of towers on the vertical plane through the axis of the structure when same is unloaded; with structure loaded, take 30 lbs. per sq. ft. of this same surface, and in addition, the moving wind load specified for girder bridges. For determining the requisite anchorage for the loaded structure, assume the train to weigh 600 lbs. per ft.—*P. & R.*

Lateral wind pressure same as Am. Br. Co. specifications with the following minimum values; Bracing of loaded chord, 500 lbs. per lin. ft., 300 of which is moving- and 200 dead load; unloaded chord, 150 lbs. per lin. ft., uniformly distributed. On viaduct towers, as seen in elevation, use 60 lbs. per sq. ft. on the loaded, and 100 lbs. per sq. ft. on the unloaded, structure.—*S. P.*

† $\frac{1}{4}$ " except for fillers.—*C. R. I. & P.* $\frac{1}{2}$ " except for fillers; 1 sq. in. in section for rods or bars; $1\frac{1}{2}$ sq. ins. for counters.—*D. L. & W.* $\frac{1}{4}$ " except for latticing and fillers; $3 \times 3 \times \frac{1}{4}$ angles.—*L. S. & M. S.*

‡ 16000 for structural steel at 60000 ult.—*C. R. I. & P.*
Soft Steel:—Bottom chords and main diagonals: Eye bars, 9000 *L. I.* 14000 *d. I.*; built sections, 8500 *L. I.*, 12500 *d. I.*; counters, 8500. Hip and

members, make net section through pin hole $1\frac{1}{2}$ of net section; and net section back of pin hole at least $\frac{1}{4}$ of net section hole.

Compressive Stresses.*—25. Compression members:

$$p = \frac{\text{Medium Steel. } 17000}{1 + \frac{l^2}{11000r^2}} \left\{ \begin{array}{l} p = \text{working load in lbs. per sq. in.;} \\ l = \text{effective length of column in ins.} \\ r = \text{least rad. of gyr. (See Table 7,} \\ \text{page 710.)} \end{array} \right.$$

exceed 100, except wind bracing, 120.—*P. & R.*

ns used as girders, and compression members with $\frac{l}{r} < 40$, same
(see S. P. foot-note above). For lengths where $\frac{l}{r} > 40$ use:—

fixed, $p = 8000 \left(1 + \frac{\text{min.}}{\text{max.}}\right) - 25 \frac{l}{r}$; for one or both ends hinged,

$\left(1 + \frac{\text{min.}}{\text{max.}}\right) - 45 \frac{l}{r}$. Steel, 60-68000 ult. No compression member
length greater than 45 times its least width.—*S. P.*

Alternate Stresses.—28. Make total area in member equal to sum of areas required for each stress.

Combined Stresses.—29. Maximum stresses due to wind and centrifugal force, added to those due to vertical loading (including impact), shall not exceed: 19000 lbs. for soft steel, or 21000 lbs. for medium steel, properly reduced for compression. 30. Reversal of stresses, if any, must be considered.

Transverse Loading of Tension or Compression Members.*—31. When the floor system rests directly on the chord, the chord member must be proportioned so that the algebraic sum of the stresses per sq. in. on outer fibre, resulting from the direct compression or tension, and $\frac{3}{4}$ of the max. bending moment (considering the chord as a beam of one panel length, supported at ends), shall not exceed the before-mentioned limiting stresses in tension or compression, the proper amount of impact being added to each kind of loading. 32. Bending moment at panel points shall be assumed equal to that at center, but in opposite direction. 33. Other members similarly affected are to be treated likewise.

Shearing and Bearing Stresses.†—34. For rivets, bolts and pins, the shearing stress per sq. in. shall not exceed 11000 for soft steel, and 12000 for medium steel; and the pressure upon the bearing surface of the projected semi-intrados (diam. $\times$ thickness) shall not exceed 22000 for soft steel, and 24000 for medium steel. (See Table 1, page 612.) 35. Increase number of rivets thus found if field driven: by hand, 25%; by power, 10%.

Bending Stresses on Pins.‡—36. Extreme fibre stress: Soft steel, 22000; medium steel, 25000 lbs. per sq. in. Use centers of bearings of strained members. (See Table 25, page 630.)

Plate Girders.||—37. Assume $\frac{1}{2}$ gross area of web as available flange area. Compression flange to have same sectional area as tension flange:

* Should the pins be out of the neutral axis, the additional stress thus produced shall be provided for.—*P. & R.*

† Shearing: Shop rivets and pins, 12000; field rivets and turned bolts, 10000; plate girder webs (gross section) 10000. Bearing: Shop rivets and pins, 24000; field rivets and turned bolts, 20000; granite masonry and Portland cement concrete, 600; sandstone and limestone, 400 lbs. per sq. in.—*C. R. I. & P.*

Shearing: Pins and rivets, 7500; web plate, 5000 in direction of rolling, and 6000 across fibre. Bearing: Pins and rivets, 12000; bed plates on masonry, 250. Decrease 25% for hand and field rivets; increase 25% for lateral and vibration riveted connections.—*D. L. & W.*

Shearing: Rivets, bolts and pins, 11000; web plates of stringers, floor beams, and plate girders (net section), 11000. Bearing: Rivets, bolts and pins, 22000; masonry, 400. Deduct 20% for field rivets.—*L. S. & M. S.* Same as preceding excepting, use 10000 for "shear in webs of plate girders."—*P. & R.*

Shearing: Pins and rivets, 7500; webs of plate girders, 6000. Bearing: Pins and rivets, 15000. Increase stresses 50% for knee bracing; decrease 20% for hand rivets.—*S. P.*

‡ 24000.—*C. R. I. & P.* and *L. S. & M. S.* 15000.—*D. L. & W.* 22000.—*P. & R.* 1800.—*S. P.*

|| Proportioned either by moment of inertia of net section; or by assuming $\frac{1}{2}$ of gross web section to be added to flange area. Gross section of comp. flange shall not be less than that of tens. flange; nor shall working stress in comp. flange of any beam or girder exceed $16000 - 200 \frac{l}{b}$, where l = unsupported distance, and b = width of flange.—*C. R. I. & P.*

Girders and beams must have top or comp. flange braced at intervals of at least 20 times the width of flange. No part of web of plate girder considered as flange area.—*D. L. & W.*

Depth of girder generally $\frac{1}{16}$ to $\frac{1}{10}$ of span up to 75 ft. span, and proportionately less up to a minimum of $\frac{1}{16}$ for the largest practicable plate girder. No part of web to be considered as flange area. No cover plate shall have a thickness greater than the angles; $\frac{3}{4}$ in. to be about the max. thickness. First cover plate to extend full length; other plates, 12" beyond theoretical cut-off. For spans over 70 ft., flange members may be spliced, only one angle at any one point of flange. Stiffener angles to be: $3\frac{1}{2} \times 3\frac{1}{2} \times \frac{3}{4}$ for spans up to 50 ft.; $4 \times 3\frac{1}{2} \times \frac{3}{4}$, 50 to 70 ft. spans; $5 \times 3\frac{1}{2} \times \frac{3}{4}$, 70 to 90 ft. spans; $6 \times 3\frac{1}{2} \times \frac{3}{4}$, above 90 ft.—*L. S. & M. S.*

but unsupported length shall not exceed 16 times its width. 38. In designing web rivets of plate girders, assume total shear at abutment as transferred into flange angles in a distance equal to depth of girder. 39. Minimum web, $\frac{3}{8}$ ". Shear, 9000 for soft steel; 10000 for med. steel. 40. Stiffeners, both sides, close flange bearings, at points of concentrated load; also, when t of web is less than $\frac{1}{8}$ of unsupported distance between flange angles, stiffeners to be spaced generally not farther apart than depth of full web plate, with max. limit of 5 ft.

Provision for Future Increase of Live Load.*—41. When live and dead load stresses are of opposite character, only 70% of the dead load stress shall be considered as effective in counteracting the live load stress.

(d.) Details of Construction.

Camber.†—42. For truss bridges, increase length of top chord $\frac{1}{8}$ " to every 10 ft. [Best: Shorten diagonals, without increasing the chord.—*Author.*]

Adjustable Members.—44. Preferably avoided.

Truss Bridges.—45. Stiff end vertical suspenders for through spans. For end panels of lower chord, preferably stiff members for single track spans.

Lateral and Sway Bracing.—48. To be compression shapes.

Diagonal Bracing.‡—50. Deck bridges shall have diagonal braces at each panel, of sufficient strength to carry half the maximum strain increment due to wind and centrifugal force.

Gusset Plates.—51. At each end of pony trusses and through plate girders, and at floorbeam of same.

Temperature.||—52. Provision for 150° F. variation.

Bolsters and Expansion Rollers.‡—53. For bridges exceeding 80 ft. span, hinged bolsters at both ends, with nests of turned friction rollers at one end. Rollers not less than 4" dia.; and pressure p , in lbs. per lin. in. of roller, not to exceed $1200 \sqrt{d}$ for steel rollers between steel surfaces (d = diam. of roller in ins.).

Bed Plates.Δ—55. Pressure on masonry, including impact, 400 lbs. per sq. in.

Rivets.—56. In direction of strain, max. pitch to be 6" or $16 \times$ thickness of thinnest outside plate, at right angles to strain, max. pitch to be $40 \Sigma \times$ that thickness. At ends of compression members, pitch not to exceed 4 diameters of rivet for a length equal to 2θ times width of member.

Tie Plates.—60. All segments of compression members connected by latticing only, shall have tie plates placed as near the ends as practicable, with length not less than greatest depth or width of member, and thickness not less than $\frac{1}{8}$ of the distance bet. the rivets connecting them to the compressed members.

* If live load be increased 70% the stress per sq. in. in any member shall not exceed $1.7 \times$ the allowed unit stress, and in case of reversal of stress proper provision shall be made for same.—*C. R. I. & P.*

† Camber for plate girders over 50 ft. span to be $\frac{1}{8}$ " per 10 ft. of length.—*C. R. I. & P.* Camber for all spans, about $\frac{3}{4}$ " in 100 ft.—*D. L. & W.* Camber for movable bridges, such that when end supports are raised to their exact position the base of rail will be at the same level on ends of bridge as at center.—*L. S. & M. S.* Arc of circle; and at least $\frac{1}{1000}$ of the span.—*S. P.*

‡ Overhead diag. bracing at each panel point when height of truss exceeds 25 ft.—*P. & R.*

|| Expansion and contraction, 1" in every 100 ft.—*D. L. & W.* and *L. S. & M. S.* 150° F.—*P. & R.* and *S. P.* $\frac{1}{8}$ " for each 10 ft.—*C. R. I. & P.*

§ Rollers not less than 6" diam.—*C. R. I. & P.* Rollers not less than $\frac{3}{4}$ " diam.; or $p = 300 d$.—*D. L. & W.* Rollers: $1200 \sqrt{d}$.—*P. & R.* For bridges over 75 ft. span, segmental steel friction rollers not less than 6" diam.; but cylindrical rollers 4" diam. may be used.—*S. P.*

Δ See, also, foot-notes to 34, preceding, for bearing on masonry.

Σ 30.—*P. & R.* θ $1\frac{1}{2}$.—*C. R. I. & P.*

	1.41	1.35	1.29	1.22	1.15	1.08	1.00

Example.—Find the approx. weight of steel in a Through Plate Girder Bridge with floor beams and stringers, span 100 ft., loading E 40?

Solution.— $l \times w = 100 (180 + 70) 6.32 = 158000$ lbs.

VIII.—PLANS AND DETAILS OF RAILROAD SPANS.

Howe Truss Bridges are being rapidly replaced by steel and concrete structures on all of our American roads, but the following typical plans will be of interest.

N. P. R'Y STANDARD PLAN OF HOWE TRUSS AND DETAILS.

90 Ft. Through Span.

Loads.—Dead Load, 1300 lbs. per lin. ft. Live Load, consolidation engine and tender, 225,000 lbs., followed by 3000 lbs. per lin. ft.

Figs. 25.—General Plan and Elevation.

Timber Specifications.—Must be sound, live, straight and close grained red or yellow fir, cut free from waness, shakes, pitch seams and clear of

knots larger than 1" dia., nor closer than 4 ft. on any side of must be sound and clear of pitch. All timber must be cut logs free from heart and sap, and sawed true to sizes ordered f. o. b. cars, subject to inspection before delivery.

Notes.—Use red fir cross-ties west of Helena. Frame sizing stringers into floor-beams. In framing, carpenters panels full size, make templates of angle blocks from the braces to correct length and shape so determined. Cast iron packing bolts in top chord are 5" dia. except for bolts in center and at ends of chords, which have separators $3\frac{1}{2}$ " dia. All other for packing bolts are $3\frac{1}{4}$ " dia. Guard rails bolted to ties middle and spiked to all other ties with $\frac{1}{2}$ " x 10" bridge fifth tie spiked to stringers with $\frac{1}{2}$ " x 14" bridge spikes.

Reinforced Concrete Bridges.—The principal use of reinforced concrete in railroad bridges is in the form of trestles and arches, wtain conditions, it is found most economical. Many useful class of construction will be found in the three following par and References." For formulas and working stresses, see and 32. See, also, other Sections and Index.

EXCERPTS AND REFERENCES.

A Graphical Method of Finding Floor-Beam Concentrations Under Wheel-Loads (By R. H. Bulloch. Eng. News, May 21, 1903).

Standard Plans for Bridges on the Atchison, Topeka & Santa Fe Ry. (By J. Dun. Eng. News, May 28, 1903).—Illustrated.

A Comparison of the Requirements of Recent Railway Bridge Specifications (By A. H. Heller. Eng. News, Nov. 19, 1903).—Tabulated data, from 29 specifications.

A New Truss Design (By J. W. Schaub. Eng. News, Mar. 24, 1904).—Warren type, with a combination of pin and riveted connections. Adopted by some of the railroads.

A Moment Table for Wheel Loads (By R. B. Ketchum. Eng. News, May 12, 1904). Table and diagrams.

New Westminster Bridge over Fraser River. B. C. (By Waddell and Herrick. Eng. News, June 15 and 22, 1905).—Foundations, superstructure and erection; illustrated.

Recent Railway Viaducts of Reinforced Concrete (Eng. News, May 31, 1906).—Illustrated.

Diagram Table for Cooper's E-50 Loading (By J. Gibson. Eng. News, June 21, 1906).—Double inset sheet. Very elaborate table.

Wheel Loadings of Mallet Duplex Compound Locomotive for Great Northern Ry. (Eng. News, Nov. 22, 1906).—Corrected diagram.

Rail Expansion Joints on the Thebes Bridge (By Ralph Modjeski. Eng. News, Aug. 22, 1907).—Illustrated.

Proportioning Steel Railway Bridge Members (By H. S. Pritchard. Eng. News, Sept. 19, 1907).

Erection of Long Span Trusses by End Launching (Can. Soc. Civ. Engrs. April 16, 1908; Eng. News, July 23, 1908).—Illustrated.

Safe Unit Stresses in Structural Timber (Eng. Rec., Apr. 24, 1909).—The safe unit stresses in structural timber recommended by the committee on wooden bridges and trestles of the Am. Ry. Eng. and M. of W. Assn., for green condition of timbers and without increasing the live-load stresses for impact, are as follows:—

	Bending.	Shearing.		Compression.		
	Extreme fiber stress.	Parallel to grain.	Long'l in beams.	Perp. to grain.	Parallel to grain.	Cols. under 15 dia's.
Douglas fir.....	1 200	170	110	310	1 200	900
Longleaf pine....	1 300	180	120	260	1 300	980
Shortleaf pine....	1 100	170	130	170	1 100	830
White pine.....	900	100	70	150	1 000	750
Spruce.....	1 000	150	70	180	1 100	830
Norway pine.....	800	130	100	150	800	600
Tamarack.....	900	170	100	220	1 000	750
Western hemlock..	1 100	160	100	220	1 200	900
Redwood.....	900	80		150	900	680
Bald cypress.....	900	120		170	1 100	830
Red Cedar.....	800			230	900	680
White oak.....	1 100	210	110	450	1 300	980

For long columns exceeding 15 diameters in length the safe stress given for compression parallel to grain are taken and decreased by $60L + D$, where L =length in ins., and D =least side in ins.

Measurement of Impact Stresses (By B. W. Dunn. Proc. A. S. T. M., Vol. 1X., 1909).

Reinforced-Concrete Bridges for Track Elevation on Ill. Cent. R. R.; Failure Test of Very Large Concrete Slabs (Eng. News, Aug. 6, 1908).—Illustrated.

Application of Spiral Hooping to a French Concrete Bridge (Eng. News, April 22, 1909).—Illustrated.

Erection of New River Bridge by the Cantilever Method (By L. L. Jewel. Eng. News, July 8, 1909).—Single-track deck structure, 2155 ft. long, 112 ft. above low water; spans, 125 to 140 ft.; all trusses are riveted Warren trusses, 26 ft. deep c.-c. chords and spaced 12 ft. apart; no floor system provided; the deck of extra heavy ties being carried directly on the top chords. Erected by cantilever traveler; 11 illustrations.

Guard Rail and Deck Construction for Railway Bridges (Eng. News, Sept. 9, 1909).

Illustrations:

Typical arrangement of bridge guards; Lehigh Valley R. R. Deck and guard rail construction (with two and three inside guards); Can. Pac. R. R. Bridge deck with sidewalk; Carolina, Clinchfield and Ohio R. R. Bridge deck construction on curves; Carolina, Clinchfield and Ohio R. R. Details of bridge deck and guards; Lehigh Valley R. R. Bridge deck with timber guards; Louisville and Nashville R. R. Bridge deck and guards (with tangents and curves); Penn. Lines. Bridge guards with re-railing devices; Southern Pacific R. R. Details of re-railing devices; Southern Pacific R. R. Re-railing devices at approaches to jack-knife draws; B. & M. R. R. Bridge guards on concrete bridge on a French railway. Deck and guard rail construction; So. Side Elev. Ry., Chicago. Deck and guard rail construction for curves; So. Side Elev. Ry., Chicago. Examples of bridge guards on English railway bridges.

Lethbridge Viaduct over the Belly River, Canadian Pac. Ry. (By J. E. Schwitzer. Eng. News, Sept. 23, 1909).—Plans of floor and tower.

Four-Track Truss Bridge with Solid Floor; Chicago & Oak Park Elev. Ry. (Eng. News, Dec. 9, 1909).—Numerous plans and details, including falsework.

Long Span Reinforced-Concrete Girder Bridges (By F. W. Scheidenhelm. Eng. News, Jan. 27, 1910).—Illustrations: Girders, abutment and piers; with details of centering and forms used on the 75-ft. girder; also, splice clamp for reinforced-concrete bars.

Reinforced-Concrete vs. Steel for Short Span Railway Bridges (Eng. News, Mar. 24, 1910).—Reinforced-concrete flat slabs or girders not generally advisable for railway loads in spans exceeding 40 feet.

450-Ft. Steel R. R. Span of the Miles Glacier Bridge, Alaska (Eng. Rec., Aug. 6, 1910).—Illustrations: Elevation of bridge (one 450' span, two 400' spans, one 300' span); truss details of 450' span; fixed and expansion end shoes, with segmental rollers and nest and grillage, 450' span; erection filler between shoes on pier; erection adjustment devices for top and bottom chords.

The St. Louis Municipal Bridge Superstructure (Eng. Rec., Dec. 3, 1910).—Bridge composed of three 668-ft. steel spans carrying two railroad tracks on the lower floor at bottom chord level, and two electric car tracks, a driveway, and two cantilever sidewalks one on second floor 22 ft. in the clear above the lower floor. The two pin-connected trusses 35 ft. apart on centers are 110 ft. deep, 65 ft. in the clear above high water and will be made of nickel steel, while the floor system and bracing will be made of carbon steel (See Eng. Rec. of Oct. 30, 1909, for diagrams, stress sheets, specifications, etc.; also Eng. Rec. of Oct. 15, 1910, for description of design and construction of the substructure.) The main span trusses are longer than those of any other span with independent trusses; the panel lengths vary with the depths of the trusses in accordance with economical inclinations of the diagonal members; the top chord has a special type of cross-section; the upper deck is made with intermediate floorbeams carried on longitudinal girders. The main truss shoes and pedestals are heavy steel castings; many of the compression members have half-hole pin-bearings without interlocking

pin plates; and the members and details are of standard construction. Illustrations:—Regular cross-section; general diagram of 668-ft. span, giving heights of truss; upper and lower portal bearing; roadway bent over pier; sections of upper and lower decks; expansion shoe and pedestal for same; pedestal for fixed shoe; top chord details of sidewalk and curb girder.

Important Illustrations of Railroad Bridges and Details.

39.—ELECTRIC RAILWAY BRIDGES.

See, also, Sec. 40, Highway Bridges, page 727.

Typical "L" Loading as follows, for electric railway bridges may be used for any structure, heavy or light, by assigning proper values to w .*

- (a) For calculation of floor system, use two axle concentrations of $15w$ each, spaced 10 ft. centers. (See Fig. 1.)
- (b) For calculation of trusses, use for each track a uniform moving load of w lbs. per lin. ft. for spans up to 100 ft.; and $0.8w$ for spans 200 ft. and over; with a reduction of loading for intermediate spans of $0.01w$ for every 5-ft. increase over 100 ft. The uniform load w per track is assumed to cover a surface 12 ft. wide for single track; 22 ft. wide for double track.

Fig. 1.

Tables 1 and 2 are based on the above typical "L" loading.

1.—SPECIAL TYPE "L" OF ELECTRIC-CAR LOADING†—AXLE AND UNIFORM.

Name.	* For the floor and its supports. Concentrated Axle Loads.	For the trusses. Uniform live load (12 ft. wide) per lineal foot of track.										
		Up to 100' span	110' span	120' span	130' span	140' span	150' span	160' span	170' span	180' span	190' span	200' span
	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.
<i>L</i>	$15w$	w	$.98w$	$.96w$	$.94w$	$.92w$	$.90w$	$.88w$	$.86w$	$.84w$	$.82w$	$.8w$
<i>L</i> 18	18,000	1200	1176	1152	1128	1104	1080	1056	1032	1008	984	960
<i>L</i> 24	24,000	1600	1568	1536	1504	1472	1440	1408	1376	1344	1312	1280
<i>L</i> 30	30,000	2000	1960	1920	1880	1840	1800	1760	1720	1680	1640	1600

Typical "K" Loading, Fig. 2, consists of a train of electric cars with axle spacing, 5'-15'-5'-15', etc., continuous. The loading shown in the subjoined diagram is for 100,000-lb. cars, each covering a length of 40 feet. Tables 3, 4 and 5, following, are calculated from this diagram.

Fig. 2.

* For the Manhattan suspension bridge across the East River, New York, the value of w was originally assumed at 1700 lbs. per lin. ft. for each of four rapid transit trains; and 1000 lbs. per lin. ft. for each of four lines of trolley cars. The revised loading is given on page 756.

† The concentrated loading gives maximum moments for spans under 48.2 feet, and the uniform loading for spans over 48.2 feet. For maximum floorbeam reactions use concentrated loading for panels up to 23.66 feet in length (2 panel span of 47.32 feet). Beyond this length uniform loading gives maximum floorbeam reaction. For maximum end shear use concentrated loading up to 54.5 ft. span, and uniform loading beyond.

2.—MAXIMUM MOMENTS, END SHEARS, AND FLOORBEAM REACTIONS R per track for concentrated "L 24" loading—24,000 lbs. on each of two axles spaced 10 feet apart.

Values for any other "L" loading are directly proportional to the axle loads.

Span Ft.	Moment M , Ft.-lbs. 	Equivalent Uniform Load w for Moment. Lbs. per lin. ft.	End Shear S , Lbs. 	Equivalent Uniform Load w for End Shear. Lbs. per lin. ft.	Floorbeam Reaction R , Lbs. 	Equivalent Uniform Load w for Floorbeam Reaction. Lbs. per lin. ft.
	For $l > 17.07$ use $\frac{.48 \cdot \left(\frac{l}{10} - \frac{1}{4} \right)}{1}$	From equation $M = \frac{w l^2}{8}$ we have $w = \frac{8M}{l^2}$	For $l > 10'$ use $S = "24" +$ $"24" (l-10)$	From equation $S = \frac{w l}{2}$ we have $w = \frac{2S}{l}$	For $l > 10'$ use $R = "24" +$ $"24" (l-10)$	From equation $R = w l$ we have $w = \frac{R}{l}$

40.—HIGHWAY BRIDGES.

I.—UNIVERSAL STRESS-SHEETS.

Explanation.

The following are types of trusses suitable for bridge spans up to about 260 ft. in length. They are designated by a figure, indicating the number of panels in the truss, and also by a distinguishing letter when more than one type of the same number of panels are used. Thus, Types 4A, 4B and 4C each have 4 panels, but their truss systems are different.

The Diagrams are proportioned by scale and show height of truss in terms of panel length $p=1$. The members of the truss are numbered in each case to correspond with the numbers in the adjoining tables. The practical upper and lower limiting spans, with resulting panel length, are given for each type. The fractions at lower chord joints express the live-load reactions, at left abutment, in terms of a panel load = unity, of panel loads from the right-hand end up to and including that joint; and are useful for finding the shears.

The Tables accompanying the diagrams give the *unit length* of each truss member for a panel length of unity (actual length = unit length $\times$ panel length); also the dead- and live-load *unit stresses* in each truss member for unit panel loads (actual stress = unit stress $\times$ panel load per truss).

Ex. 1.—What type of truss would be suitable for a 168-ft. span? Find the lengths of the members? Find maximum stresses in members 11 and 16?

Solution.—Type 8; 8 panels @ 21 = 168. Height = $21 \times 1\frac{1}{2} = 28$. Diagonals = $21 \times 1\frac{1}{2} = 35$ ft. Assuming dead-load at 1000, and live-load at 1200 lbs. per lin. ft. of bridge, the respective panel loads per truss are: d. l. = 10.5 and l. l. = 12.6 thousand lbs.; whence the max compressive stress in 11 = $1.5 \times 10.5 + 1.875 \times 12.6 = 39,375$ lbs., and the max tensile stress in 16 = $-.625 \times 10.5 + .938 \times 12.6 = 5,256$ lbs.

Types of Trusses, and Unit Stress Sheets.

[See Explanation, preceding].

c = compression; t = tension.

Type 2A.

For spans 36' to 40'.

2 @ 18' = 36'.

2 @ 20' = 40'.

.795c	2.007	1.	1.338	1.	.669	.669 c	0	1.338 c	.628r	1.711 c
.583r	3.122	1.	2.453	1.833 c	.669	1.672		1.115	.628r	1.222r

Notes.—Using "balanced loads," the tension of 0.6 in member 15 is obtained from live loads P_1, P_2, P_{10} and P_{11} . Tension of 0.583 in member 20 is obtained from live loads $P_1, P_2, P_4, P_8, P_{10}$ and P_{11} . Compression of 1.567 in member 20 is obtained from live loads P_1 to P_9 inclusive, omitting P_8 . In the last calculation note that the cutting plane will cut *four* active members, 9, 28, 20 (27 inactive) and 5, with the center of moments at O' . But the stress in member 28 is one-half the panel load P_9 multiplied by the secant of its angle of inclination = $.5 \times 1.257 = 0.628$, and the moment of this stress about O' is 5.138. This enables us to solve the stress in member 20 by cutting the *four* active members. Thus, stress in member 20 = $\frac{1}{4} (-R_1 \times 8 - 5.138 + P_9 \times 11) = -1.567$.

Roadway.—For alternative or concentrated "L" loading given in Table 13 see Fig. 1, page 716; also Tables 1 and 2, pages 716 and 717, and Tables 14 and 15, pages 728 and 729.

NICKEL-STEEL AND CARBON-STEEL SPANS.

following, has been condensed from very extensive and red data in the author's forthcoming structural handbook. ers a range of span lengths from 40 to 200 feet, with 5 ft. respective live loads for the same length of span were selected eight of trusses would be about equal. In the nickel-steel al systems are of carbon steel, the floor-beams and trusses steel. Although two different specifications were used—one steel and one for the nickel-steel spans—the comparative total amount of steel are not materially affected.

Costs are based on the following prices:

el, delivered, at 4½ cents per pound;

, delivered, at 6 cents per pound;

livered, at \$35 per M. ft., B. M.;

carbon-steel span, cost in dollars = $2 \times \text{span in feet} + 0.003$

at of metal in lbs.;

nickel-steel span, cost in dollars = $2.1 \times \text{span in feet} + 0.003$

at of metal in lbs.;

st in dollars = $\frac{1}{2} \text{ the span in feet} + 0.001 \times \text{weight of metal in lbs.}$

-steel spans have a 3" wooden floor on wooden joists; the ns have an additional covering of flooring plank, 2 ins. thick. n of the table, below, shows that while the nickel-steel spans to 40% more than the carbon-steel spans, yet their live-load m 60 to 80% greater, thus showing a decided economy in el-steel—based on the above assumed prices. As none of ls are prepared to engage in the general manufacture of structures at the present time, however, the estimated costs ered as being more or less approximate.

Calculations used in proportioning the principal members of the as follows:

CARBON STEEL.

ord, main diagonals, counters and long verticals, tension:

live stress + $\frac{1}{2}$ dead stress) $\div 12500$.

compression:

live stress + $\frac{1}{2}$ dead stress) $\div (12000 - 55 \frac{l}{r})$.

(inclined), compression:

live stress + $\frac{1}{2}$ dead stress) $\div (11000 - 50 \frac{l}{r})$.

te posts (vertical), compression:

live stress + $\frac{1}{2}$ dead stress) $\div (10000 - 45 \frac{l}{r})$.

s—bottom flange of riveted girder, tension:

et) = (live stress + dead stress) $\div 13,000$.

NICKEL-STEEL.

ord, main diagonals, etc.—eye bars—tension:

live stress $(1 + P) + \text{dead stress}$ $\div 30000$.

compression:

live stress $(1 + P) + \text{dead stress}$ $\div (30000 - 130 \frac{l}{r})$.

(inclined), compression:

live stress $(1 + P) + \text{dead stress}$ $\div (30000 - 140 \frac{l}{r})$.

te posts (vertical), compression:

live stress $(1 + P) + \text{dead stress}$ $\div (27000 - 160 \frac{l}{r})$.

s—bottom flange of riveted girder, tension:

et) = (live stress $(1 + P) + \text{dead stress}$) $\div 24000$.

NOTATION.

l and r = length and radius of gyration of member, in ins.

P = percentage of impact for live-load stress,

in formula, $P = 10000 \div (150 + \text{length of span, in feet, or portion of span covered by live load when the member considered is subject to maximum stress.})$

35.—COMPARISON OF CARBON-STEEL AND NICKEL-STEEL SPANS, 40-200 Ft. ROADWAY, 20 FEET WIDE.

V.—REINFORCED CONCRETE BRIDGES.

Design and Cost of Reinforced-Concrete Highway Bridges (By A.N. Johnson. Paper, Ill. Soc. Eng'rs and Surveyors, Jan. 26, 28, 1910; Eng. News, Feb. 10, 1910).—Summary of cost per cu. yd. of concrete is as follows:

Cement.....	\$2.35 to \$1.25
Stone.....	3.23 " 1.30
Sand (excluding gravel concrete).....	1.47 " .32
Gravel.....	2.43 " .70
Forms.....	3.95 " .83
Steel in place.....	3.10 " .80
Mixing and placing concrete.....	2.72 " .72
Excavation.....	3.91 " .21

Total.....\$17.51 " \$6.54

Spans range from 7 ft. to 60 ft., roadways mostly 16 ft., abutments mostly 10 to 13 ft. high. Extensive cost table not reproduced here.

41.—CANTILEVER BRIDGES.

In True Cantilever Bridges the stresses are statically determinate, and to American engineers this type offers weighty advantages over the continuous-girder* types generally adopted by European engineers. Let us assume an ordinary form of cantilever as per Fig. 1, with a free central span l suspended

Fig. 1.

at the points b and b' , introducing in the cantilever at those points the downward forces R_1 and R_1' . R_1 produces a downward reaction $R_3 = \frac{R_1 l_1}{l_2}$, and an upward reaction $R_2 = \frac{R_1 (l_1 + l_2)}{l_2}$; and similarly with R_3' and R_2' .

Reaction R_3 is upward when l_2 is loaded direct, and likewise with R_3' when the loading is on l_2' . Hence to resist both kinds of reaction, upward and downward, at the ends of the bridge, anchorages as well as piers or supports are required (see Fig. 2); while at R_2 and R_2' , supports only are needed.

In erection, the spans are built outward from the abutments in cantilever fashion to the central point o ; hence the lower chords out to the points a and a' must be stiff members to resist compression, while bc and $b'c'$ are introduced as tension members. For any load P on span l_1 the reactions R_3 and R_2 may be obtained as above, but by using Px instead of $R_1 l_1$. Any loading on l_2 can affect only that span. The usual problem is to (1) find the loading which will give the maximum (+ and -) stresses for each member; (2) find the required reaction; and (3) solve as in ordinary trusses. For instance, the maximum compressive stress in the end post E obtains with l_2 full loaded (l_1 and l unloaded); but for maximum tensile stress in that member the reverse loading obtains, l_1 and l loaded (l_2 unloaded).

The position of loading for reactions at supports, and also for maximum stresses in members, may sometimes be studied conveniently by the use of influence diagrams. Fig. 2 is such an influence diagram, and shows the

Fig. 2. Reactions R_3 for Left Support.

reaction R_3 for a load moving from the right-hand end of the central span l .

* The writer knows of but one steel truss bridge in America built on the continuous girder principle, excepting of course draw bridges. This is the O. R. & N. R'y Co.'s bridge across the Willamette river at Portland, Oregon. On the other hand, the statically indeterminate types prevail in Europe.

toward the left-hand anchorage, over l , l_1 and l_2 . The reactions R_1 , for successive positions of the concentrated load, are shown by the ordinates at the point *where the load is applied* on the structure (see Fig. 1); downward when load is on l and l_1 , and upward when load is on l_2 .

Carbon-steel cantilever spans are economical, generally, up to about 1600 to 1700 feet; nickel-steel spans, up to about 1900 or 2000 feet. Beyond these spans, suspension bridges become more economical. Much depends on local conditions.

The limiting length of carbon-steel cantilever spans is practically about 2000 feet; and of nickel-steel cantilever spans, about 2500 feet.

Deck Cantilever Bridges are economical in certain localities where there is sufficient head-room over the street, valley or stream to be bridged. Fig. 3 is typical. The general outline is practically an invert of Fig. 1.

Fig. 3.

The stresses in the truss shown in Fig. 3 are rendered statically determinate by making slotted pin-holes at S , inserting pins at all lettered points, and providing a roller end at R . F is the fixed end.

Camber.—In providing for camber the simplest method, and the best for erection, is to raise the panel points by shortening the diagonals, maintaining all vertical posts mathematically parallel.

42.—MOVABLE BRIDGES.

Movable Bridges are designed to provide temporary openings for one line of traffic (usually a waterway) which is crossed by another (usually a street or railway). There are five distinct types, as follows:

(1). Swing Bridge or "Drawbridge"—balanced and swinging horizontally round an arc (usually a quadrant) of a circle: (a) Equal spans or arms, supported by pivot pier; (b) One span, counterpoised; (c) Two spans counterpoised.

Type (1a) is discussed below.

(2). Traversing Bridge—counterpoised tail-end raised from its supports and span drawn back on rollers along one of its approaches. Used principally for narrow openings.

(3). Bascule Bridge—tail-end ballasted with cast iron and lead and span swinging vertically: (a) One arm; (b) Two arms, either with tail-ends together, or like a jack-knife with two blades hinged at either end. The bascules are raised and lowered by pinions (operated by hydraulic, electric, steam, gasoline or other power) working in segmental racks.

(4). Lift Bridge—whole span raised vertically by chains, at the four corners, suspended from towers. Counterpoised weights are used in order to reduce the required power for operating.

(5). Floating or Pontoon Bridge—iron pontoons (usually rectangular) coupled in pairs for stability and moored at all corners. Bridge is opened to river traffic by the use of running back drawbridges. This type of bridge is used where foundations for piers would be difficult and excessively expensive.

SWING BRIDGES.

Drawbridges may be either rim-bearing or center-bearing.

The *rim-bearing draw*, with each truss supported at two points on the center pier, is the more common type of the two. This is shown in Fig. 1, the center points of support for the trusses being at *a b c d*, irrespective of the diameter of circular drum or turntable. Usually the circular drum is of such diameter as to give support to the center panel of draw at 8 equi-distant or nearly equi-distant points, as shown in the figure. In such a case heavy girders, acting as cantilevers, are introduced in the chords *ab* and *cd* and in the floor-beams *ad* and *bc* in order to distribute the loads more uniformly on the table. These cantilevers may be designed sufficiently strong to carry the live and dead loads, or only sufficient to carry the dead load, in which latter case adjustable supports may be introduced at points *a b c d* to transmit the *live* loads directly from trusses to center pier when draw is closed. In either event the center pier supports are at *a b c d* so far as the calculation of trusses is concerned, and when the draw is closed each truss becomes a continuous girder of 3 spans over 4 supports, for any moving load on the draw.

Fig. 1.

The *center-bearing draw* differs from the rim bearing in that the weight is supported at the center either (1) on a vertical, steel pivot pin, or (2) on a nest of conical rollers. The weight is transferred to the center from the trusses by means of transverse superimposed girders between the chords, a light turntable being used to "steady" the span in revolving, but not calculated to give material support. When the draw is closed each truss becomes a continuous girder of two spans over 3 supports, for any moving load on the draw; and such *live* load may be supported, if desirable, by adjustable wedges placed at the middle of draw under the trusses.

For the calculation of swing bridges three cases* or conditions are usually employed in determining the stresses, as follows:

- I. Each arm treated as a simple span resting on two supports, with live-, dead- and wind loads acting.
- IIa. Bridge swinging and treated as a cantilever, with dead- and wind loads acting, and with reactions at center supports only.
- IIb. Bridge closed and treated as a continuous girder over all supports, with live load acting. It is assumed in this case that the vertical reactions at ends of draw are ± 0 when no live load is acting. The live load is considered as "balanced," that is, it advances symmetrically on both arms from the ends toward center of span.

For maximum stresses in the truss members use Case I, or Cases IIa and IIb combined, whichever gives the maximum. For maximum stresses in the lateral systems use each of the cases separately and select that stress which is a maximum for each member. In case there is a reversal of stress in any member, two maxima will be required, one in tension and one in compression. Some specifications make it necessary to determine minimum as well as maximum stresses, in which case it is evident that, for the trusses, Case IIb cannot be used alone.

Rim-bearing Draw—4 Supports.—For Case I with the draw considered as two simple spans, and Case IIa as a cantilever, the reactions at the supports are obtained easily and the stresses in the members are statically determinate. For Case IIb, however, it is treated as a continuous girder which takes the form of an elastic curve when loaded. The girder is assumed to be of homogeneous material with constant modulus of elasticity, E ; constant cross-section or rather moment of inertia, I ; and resting on level supports. As a matter of fact none of these exact conditions actually obtain in practice. The necessary reactions at the supports due to any loading on the continuous girder are deduced from the "theorem of three moments."

Reactions at the Supports—Continuous Girder.—Let P be any concentrated load, Fig. 2, on the left arm, distant a from the end; then will

Fig. 2.

$$R_1 = P \left(1 - \frac{a}{l} \right) \left[1 - \left(1 + \frac{a}{l} \right) \frac{\frac{2l}{c}}{4 \left(\frac{l}{c} + 1 \right) - \frac{1}{\frac{l}{c} + 1}} \right] \dots \dots \dots (1)$$

$$R_4 = P \left(1 - \frac{a^2}{l^2} \right) \frac{\frac{l}{c}}{4 \left(\frac{l}{c} + 1 \right)^2 - 1} \dots \dots \dots (2)$$

$$R_3 = \left[R_1 - R_4 - P \left(1 - \frac{a}{l} \right) \right] \frac{l}{c} - R_4 \dots \dots \dots (3)$$

$$R_2 = P - (R_1 + R_4) - R_3 \text{ (algebraically)} \dots \dots \dots (4)$$

Of course it is clearly evident that if the load P is on the right arm instead of the left, and distant a from the right hand end, the resulting reactions will be interchanged— R_1 with R_4 , and R_2 with R_3 . Hence, for balanced loads, that is, the same loading in position and amount on both arms, each end-support reaction will equal $R_1 + R_4$, and each center-support reaction will equal (algebraically) $R_2 + R_3$ for the specified load on either arm. In drawbridge calculations P is the panel load and a the distance from end of draw to each consecutive panel point where the load acts. When the reactions are known the stresses in the structure may be solved by the ordinary methods.

***Assumptions for cheap highway drawbridges.**—Various assumptions are made for cheap swing bridges as follows: Case A. Draw swinging and treated as a cantilever, as in Case IIa above. Case B. Draw closed and end raised to support say $\frac{3}{4}$ the dead load of one panel; and acting as a continuous girder for the live load.

It is to be noted that the length c of the center panel (over the pier) affects the values of the reactions. Preferably, c is made equal to the distance between the trusses unless this is so great as to require too large a turntable. It is also usually equal to about one panel length of truss. The following Table of reactions is based on c —one panel length of truss, and will be useful for general reference.

1.—REACTIONS R_1 , R_4 , R_3 AND R_2 FOR DRAWBRIDGE SPANS OF 2 TO 10 PANELS IN EACH ARM; WITH CENTRAL PANEL c EQUAL TO ONE PANEL LENGTH OF TRUSS; AND LOAD P EQUAL TO UNITY.

See Fig. 1, and Formulas (1), (2), (3), and (4).

Fig. 3.

Example.—For $l=9$ (panels), and with Loads at A, B and C on each arm, the end reactions are 2.068 times a panel load; and center reactions, 0.932. Moments M_2 and M_3 are -2.39 times a panel load times a panel length.

CALCULATION OF 315-FT. DRAW. (FIG. 4, PAGE 746.)

Figs. 5, 6, 7 and 8 are stress diagrams.

Fig. 5 (Case I) shows one arm treated as a simple span, fully loaded. Similar diagrams must be drawn for live load retreating, panel by panel, from end of span toward center.

Fig. 6 (Case IIa) is a dead-load stress-diagram of one arm when both arms are swinging clear of end supports.

Fig. 7 (Case IIb) is a stress-diagram for full live load when draw is closed; the condition being that ends of arms are simply touching supports under the dead load only. Similar diagrams must be drawn for live load symmetrically retreating, panel by panel, from the pier ends of arms.

Fig. 8 (Case IIb) is a stress-diagram of a retreating load last mentioned—with symmetrical loads at panel points A, B, C and D, for maximum stress in member 17.

Wind-load stress diagram can similarly be drawn.

See, also, page 742.

Fig. 4. 315-Ft. Draw.

Fig. 5.

CASE I—SIMPLE SPAN—
Full Loaded—Live or Dead.

Fig. 6.

CASE IIa—DRAW SWINGING—
Cantilever—Dead Load only.

(Stress in 24-25 = $\frac{M}{h} = 7 + 2\frac{1}{2} = 11$.)

Load at end, *a*, is $\frac{1}{2}$ of Panel Load.

Fig. 7.

CASE IIb—CONTINUOUS SPAN—
Full Loaded—Live Load.

$R_1 = 2.296$; $R_2 = 3.704$;

$M_2 = 4.93$. Stress in 24-25 =

$4.93 \div 2\frac{1}{2}$

= 2.11. (See Table 2.)

Fig. 8.

CASE IIb—CONTINUOUS SPAN—
Loaded (A, B, C, D, both arms) for
Max. Live Load in 17.

$R_1 = 2.105$ (See Table 2).

Center-bearing Draw—3 Supports.—This differs from the rim-bearing draw in having one support at the center pier instead of two. Hence, Case IIb (the only variation from the preceding illustrations) will be treated as a continuous girder of *two* equal spans over three supports.

Reactions at the Supports—Continuous girder.—Let *P* be any concentrated load, Fig. 9, on the left arm, distant *a* from the end; then will

$$M_2 = -\frac{Pa}{4} \left[1 - \frac{a^2}{l^2} \right]$$

$$R_3 = -\frac{Pa}{4l} \left[1 - \frac{a^2}{l^2} \right]$$

$$R_2 = +\frac{Pa}{l} + \frac{Pa}{2l} \left[1 - \frac{a^2}{l^2} \right]$$

$$R_1 = +P \left(1 - \frac{a}{l} \right) - \frac{Pa}{4l} \left(1 - \frac{a^2}{l^2} \right)$$

$$[= R_3 l] \dots \dots \dots (5)$$

$$\left[= \frac{M_2}{l} \right] \dots \dots \dots (6)$$

$$\left[= \frac{Pa}{l} - 2R_3 \text{ (algebraically)} \right] \dots (7)$$

$$\left[= P \left(1 - \frac{a}{l} \right) + R_3 \text{ (algebra'y)} \right] \dots (8)$$

Fig. 9.

The right hand half of the following table is all that is necessary in Case IIb of drawbridge calculations, the first half being interesting as a study of the continuous girder of two equal spans for any concentrated loading. It is to be noted that for loading on right-hand arm, R_1 and R_3 will be interchanged.

3.—PRACTICAL DATA FOR DRAWBRIDGE CALCULATION, 3 SUPPORTS. CASE IIb.

Reactions and Moments for Balanced Loads.

Reactions are in Terms of Unit Panel Load. Moments are at Center Support and are for Unit Panel Loads and a (Respective Distance from End Support). Balanced loads are Symmetrical Loads, Both Arms.

Concentrated Loads on Left Arm, Distant a From End.					Balanced Concentrated Loads on Both Arms, Distant a From Ends.

Fig. 10.

Example.—Solve for one load $P = 16000$ lbs. on left arm; $l = 45$ ft.; $a = 17$ ft.

Solution.— $\frac{a}{l} = \frac{17}{45} = .378$; $M_2 =$

$-.214 \times a \times P = -.214 \times 17 \times 16,000 = -58,200$ ft.-lbs.; $R_1 = .542 \times 16,000 = 8,672$ lbs.; $R_2 = .539 \times 16,000 = 8,624$ lbs.; $R_3 = -.081 \times 16,000 = -1,296$ lbs. (R_3 acting downward.)

Fig. 11.

Example.—Solve for load $P = 16,000$ lbs. on each arm; $l = 45$ ft.; $a = 17$ ft.

Solution.— $M_2 = -.428 \times 17 \times 16,000 = -116,400$ ft.-lbs.; $R_1 = R_3 = .46 \times 16,000 = 7,360$ lbs.; $R_2 = 1.08 \times 16,000 = 17,280$ lbs. (All reactions acting upward.)

Note.—A minus bending moment ($-M_2$) means tension in top flange or chord, and compression in bottom.

DECK DRAWBRIDGE—CENTER BEARING.

Fig. 12.

Hints for Calculation of Trusses.—In Fig. 12, let P = panel load per truss at A, B, C, D and E ; and let $\frac{3}{2}P$ = dead load at a when draw is swinging.

Case I—Simple Span.—Ends at a are raised so there is no stress in DE . For dead load and full live load the shear in panels $a-A$ and $D-E$ are equal. Maximum compressive stress in 10 occurs with live loads at B, C and D .

Case II—Cantilever.—Draw swinging, assuming $\frac{3}{2}P$ panel load at a and full panel load at other points. Shear at $D-E$ which is used for R_2 in this case = $4\frac{1}{2}P$. Stress in $D-E = 13\frac{1}{2}P \times \frac{P}{h} = 13\frac{1}{2}P$.

Case III—Continuous Girder.—Draw closed and just touching supports, with no live load. Balanced live loads are now applied on both arms, extending from ends toward center of draw. The reactions and moments for this loading may be obtained from the preceding table, as it now becomes a continuous girder of two equal spans over three "level" supports.

For loads at $A, \frac{a}{l} = .20; R_1 = .704; \frac{1}{2}R_2 = .296; M_2 = -0.48a = -0.48p$.

For loads at $B, \frac{a}{l} = .40; R_1 = .432; \frac{1}{2}R_2 = .568; M_2 = -0.42a = -0.84p$.

For loads at $C, \frac{a}{l} = .60; R_1 = .208; \frac{1}{2}R_2 = .792; M_2 = -0.32a = -0.96p$.

For loads at $D, \frac{a}{l} = .80; R_1 = .056; \frac{1}{2}R_2 = .944; M_2 = -0.18a = -0.72p$.

For loads at $A, B, C, D, R_1 = 1.400; \frac{1}{2}R_2 = 2.600; *M_2 = -3.00p$.

Note that all calculations can be made for any loading when R_1 is known, for we have only to apply the methods of moments and shears from the *outer forces* acting to the left of the section considered, to obtain the stress in any member.

WEIGHT OF STEEL IN MOVABLE BRIDGES.

Steel Swing Bridges.—The following formula is for single track standard R. R. bridges calculated for live load of two 160-ton engines followed by a uniform load of 4600 lbs. per lineal foot: Total weight of steel in lbs. = $7.8L^2 + 12(L \times \sqrt{L}) + 100L + 20000$; in which L = extreme length of draw in feet. For double track bridges, multiply results obtained in above formula by 1.85.

Counterweight Jack-knife Draw.—In Fig. 13, let l = the span HE , hinged at H and connected at D_1 (distant l_1 from H) by the chain $C + C_1$ running over the pulley P , with the cylindrical counterweight W_1 , suspended at the other end and rolling along the modified cycloidal plane AP . Assume the total weight of the movable leaf to be W acting at the point G . Then we have the following;

Weight of counterweight $W_1 = \frac{Wl\sqrt{2}}{2l_1}$;

Length of chain $C_1 = l_1\sqrt{2} \left(1 + \sin \frac{\theta}{2} - \cos \frac{\theta}{2}\right)$.

Fig. 13.

*Hence, for full loading, both arms, stress in $D-E = 2M_2/h = -3 \frac{P}{h} = -3 \times 1 = -3$ (panel loads).

le Bridges.—The weight of double track bascule bridges for 120 ft. varies from about 2000 to 6000 lbs. per lin. ft. of bridge, on the type and loading. The counterweights often weigh as much as the bridge itself.

43.—SUSPENSION BRIDGES.

THEORETICAL CONSIDERATIONS.

Curve of Main Cables.—The curve assumed by the main cables of a suspension bridge when the latter is uniformly loaded, is called a *modified* or *transformed catenary*. This curve lies somewhere between the *catenary* and the *parabola*. When the cables are first suspended between the bridge towers (before they support any extraneous load) they form a true *catenary*, due to the weight of the cables alone, assuming of course that they have a uniform weight per lineal foot of cable. But later, when the floor of the bridge is in position, that is, suspended from the main cables, the curve of the cables is "modified" and tends to *approach* the parabola in form. The true parabola, however, is hardly ever realized, the ideal condition for this curve obtaining only when the *horizontal* combined loading per lineal foot on the cables (including weight of cables themselves) is *uniform*.

For Short Spans, where weight of cables is small compared with weight of floor, we may assume for all practical purposes that the main cables take the form of a parabola; also bearing in mind that on this assumption the error decreases as the ratio of central deflection to length of span decreases. Indeed, even the arc of a circle may be used in the drafting room and also for the purpose of making estimates, when the central deflection is only $\frac{1}{2}$ or even $\frac{1}{10}$ the span. See also Tables 1 and 2.

In the above discussion of the modified catenary and the parabola it is assumed that the suspenders transmitting the loads to the cables are vertical, uniformly spaced horizontally, and *very close* together, so that the cables form true and continuous curves throughout, between points of supports. But in actual practice the suspenders are not always vertical and are usually spaced quite far apart, tending to further modify these curves.

Force Polygons.—The following force polygons assume that the cables or chords of the equilibrium polygon have no weight, being acted upon by outside forces only.

Figs. 1.

Figs. 2.

The Parabolic Cable.—Horizontal Uniform Load.—Let w = uniform load, in lbs., per lineal foot of bridge; l = span, in feet; c = half span; s = length of cable between towers; θ = angle of inclination of tangent at any point p whose coordinates are x and y ; d = center deflection of cable; constant H = horizontal component of tension (lbs.) of cable at any point p . Then with vertical suspenders, we have:

General equation,

$$y = \frac{wx^2}{2H} - \frac{4dx^2}{l^2} \dots \dots \dots (1)$$

Horizontal tension (when $x=c$, $y=d$), $H = \frac{wl^2}{8d}$, $H = \frac{wl \cdot l}{8d}$ (2)

Fig. 3.

At any point p , $\tan \theta = \frac{wx}{H} = \frac{8dx}{l^2}$ (3)

At top of towers, $\tan \theta_1 = \frac{4d}{l}$ (4)

Length of cable, $s = \frac{c}{m} \sqrt{m^2 + c^2} + 2.302585m^* \log \left(\frac{c + \sqrt{m^2 + c^2}}{m} \right)$ (5)

in which $m = \frac{H}{w} = \frac{l^2}{8d}$; $c = \frac{l}{2}$; $\frac{c}{m} = \frac{4d}{l} = \tan \theta_1$.

Tension in cables at any point $p = H \sec \theta = \frac{wl^2}{8d} \sec \theta$ (6)

Tension in cables at top of towers $= \frac{wl}{8d} \sqrt{l^2 + 16d^2}$ (7)

Tension in cables at top of towers is greater than at points between, being the least at point of greatest deflection. Hence by the use of equation (7) we may determine the size of cables required; and their weight per lineal foot multiplied by the value of s in equation (5) will give the weight of suspended cable between towers.

For mid-span, equation (6) reduces to $H = \frac{wl^2}{8d}$ (8)

Fig. 4.

The Catenarian Cable—Load Uniform Along Cable.—In Fig. 4 let l = span, in feet;

c = half span;

d = center deflection;

s = length of suspended cable between towers;

w_1 = weight of cables per lin. ft. of s ;

θ = angle of inclination of tangent at point p whose coordinates are x and y ;

H = constant horizontal component of tension (lbs.) in cable at any point p ;

h = maximum value of ordinate $y = d + m$; $m = \frac{H}{w_1} = \frac{A}{s}$;

A_x = area of shaded portion of length x , above directrix.

$A = ms$ = total area for length l , between catenary and directrix;

$\dagger e = 2.7182818$ = base of Napierian system of logarithms.

Then for equation of the catenary, we have:

General equation, $y = \frac{m}{2} \left(e^{\frac{x}{m}} + e^{-\frac{x}{m}} \right)$ (1)

where $m = \frac{A}{s} = \frac{H}{w_1}$ = horizontal tension of cable..... (1a)

But as A , s and H are functions of m itself we have to resort to other methods to find the value of m . Thus:

The approximate value of $m = \frac{x^2}{2(y-m)} = \frac{c^2}{2d} = \frac{l^2}{8d}$ (1b)

which may be substituted for value of m in the second member of equation (1c) to obtain its more nearly correct value.

Exact value of $m = \frac{0.4342945 c}{\log \left(\frac{d+m}{m} + \sqrt{\left(\frac{d+m}{m} \right)^2 - 1} \right)}$ (1c)

*Common logarithm. $2.302585 = \frac{1}{\log e}$; in which e is the Naparian base =

2.7182818 . $\log 2.302585$ is 0.3622157 .

$\dagger \log e = 0.4342945$; $\log (\log e) = 9.6377843 - 10$. Also note that

$e^{-\frac{x}{m}} = \frac{1}{e^{\frac{x}{m}}}$, in the general equation of the catenary.

when the *exact* value of m is substituted in the second member; but when m from equation (1b) is substituted, the result from (1c) is *too small* by about its excess over that obtained from equation (1b) alone. In the following table, column c_1 is obtained by adding this excess, i. e., the difference between values in columns b and c , to the values in column c . Column "diff." is a difference column, omitting the decimal point, between c_1 and c , the latter containing exact values of m ; and is useful in making corrections to values in column c_1 obtained by the approximate method as above described, for any values of $\frac{d}{l}$.

Remarks.—To find values of m (column e) for values of $\frac{d}{l}$ intermediate to those in the table: Calculate for column c_1 and subtract the interpolated difference in column "diff."

$$\text{Length of arc } s = \frac{m}{2} \left(e^{\frac{x}{m}} - e^{-\frac{x}{m}} \right) = m \tan \theta \dots \dots \dots (2)$$

Substituting c for x in above equation, we have, when towers are of equal height,

$$\text{Total length of cable } s = m \left(e^{\frac{c}{m}} - e^{-\frac{c}{m}} \right) = 2 m \tan \theta_1 \dots \dots \dots (3)$$

2.—LENGTHS s OF CABLE IN THE CATENARY, BASED ON l —UNITY.

* See foot-note, following page.

curve at point p (Fig. 4) is: $\tan \theta = \frac{1}{2} \left(e^{\frac{x}{m}} - e^{-\frac{x}{m}} \right) = \frac{s_x}{m} \dots (4)$

curve at top of tower is: $\tan \theta_1 = \frac{1}{2} \left(e^{\frac{s}{m}} - e^{-\frac{s}{m}} \right) = \frac{s}{2m} \dots (4a)$

between catenary and directrix (equa. 1a): $A = ms = \frac{sH}{w_1} \dots (5)$

component of tension in cable: $H = \frac{Aw_1}{s} = mw_1 \dots (6)$

tial tension at any point $p = H \sec \theta = H \sqrt{1 + \left(\frac{s_x}{m} \right)^2} \dots (7)$

tial tension at top of tower $= H \sec \theta_1 = H \sqrt{1 + \left(\frac{s}{2m} \right)^2} \dots (8)$

Skeleton Arch, acted upon by gravity, if constructed on the catenary (inverted), will possess maximum stability because the resultant pressure throughout the arch will coincide with the center of gravity.

Solution of the Catenary.—Fig. 5 is a graphical representation of the catenary. The theory is correct provided the load line is divided into a number of divisions—the more divisions the greater accuracy. Figures 1-6 (Fig. 5) represent the load line divided into five equal parts (from tower to point of suspension) or $\frac{w_1 s}{2}$. Lay off H from 6 to 0,

horizontal component of tension in cable will be the angle which the direction of tension makes with the horizontal at top of tower;

$\frac{s}{H} = \frac{s}{2m}$. Divide the load line into five equal parts, the more the better for accuracy. From this force polygon the equilibrium curve may be drawn: Draw 1', equal in length to cable weighing $\frac{1}{2}$ part, parallel to 2-0; draw 2', equal in length to the length of cable weighing one part, parallel to 3-0; similarly draw 3', equal to 2', draw 4', parallel to 5-0; draw 5', parallel to 6-0; and lastly, draw 6', equal in length to 5-0. Then the curve 1-E', shown imperfectly dotted, is the equilibrium curve.

Now instead of dividing the load line into five parts as above, it is possible to divide it into an infinite number of parts, we should draw a force polygon the true catenary curve 1-E for the equilibrium curve; and if 1-E represents the half length $\left(\frac{s}{2} \right)$ of the cable, the middle ordinate m will represent the length of cable weighing $w_1 m$ will be equal to the tension H , at E.

From the construction of Fig. 5 it is evident that the stress in cable is 2-0; in 3' is 3-0; etc.

If the weight w_1 of the cable is assumed as unity then 1-E will be equal in length, and m will equal H .

Formed Catenary.—This curve applies as well to the arch as the catenary bridge (see Sec. 44, Arches). The general equation of the catenary is

$$y = \frac{a}{2} \left(e^{\frac{x}{m}} + e^{-\frac{x}{m}} \right) \dots (9)$$

component, $e^{\frac{x}{m}} = 1 + \frac{x}{m} + \frac{x^2}{2m^2} + \frac{x^3}{2 \times 3m^3} + \frac{x^4}{2 \times 3 \times 4m^4} \times \dots$

$e^{-\frac{x}{m}} = 1 - \frac{x}{m} + \frac{x^2}{2m^2} - \frac{x^3}{2 \times 3m^3} + \frac{x^4}{2 \times 3 \times 4m^4} - \dots$

page.

exactly, $= \frac{w_1 l^2}{8d} \left(1 + 0.16 \frac{d}{l} \right)$, very nearly, $= \frac{w_1 l^2}{8d}$, approx.

Fig. 5.

Comparing equations (1) and (2) we note that any ordinate y of the transformed catenary $= \frac{a}{m}$ times y of the true catenary, for constant values of x and m .

In fact the catenary is a special case of the transformed catenary where $a = m$, just as the circle is a special case of the ellipse where the semi axes a and b become equal to each other and are called r , the radius of circle.

In Fig. 6, let $ABCD$ be the diagram of a catenary, similar to one-half of Fig. 4. The curve AB is that due to the weight w_1 per lineal foot of the cable itself. Now if there is an additional weight w' per horizontal lineal foot imposed upon the cable the latter will assume the exaggerated form AB' , the middle ordinate will become a , and the directrix, FE . Let s_x be the length of curve from A to any point p' , whose coordinates are x and y . Then will the load on s_x be proportional to the area $Ap'GF$, in the same way that the load on the arc Ap of the true catenary is proportional to the area $ApkD$.

Fig. 6.

PRACTICAL HINTS.

Cables or Chains.—These may be composed of wire cables or of steel eye-bars, as follows: (1) For short spans, twisted wire ropes are generally preferred as they can be manufactured and handled conveniently. (2) For spans of moderate lengths, strands composed of parallel wires, laid together near the bridge site and then hoisted into position, possess an advantage in economy of material over twisted strands, which latter develop only about 90% of the strength of straight wires. (3) For very long spans, the cables are made up of parallel wires as in the second case, but they are built in place as it would be impossible to raise them bodily on account of their great weight. (4) Steel eye-bars may be used instead of wire cables, as at first proposed* for the Manhattan suspension bridge over the East River, New York. This bridge to be composed of a central span of 1,470 ft., and two end spans of 725 ft. each. The four main chains to lie in vertical planes 20 and 48 ft. distant from the axis of the bridge. The eye-bars to be of nickel steel, $3\frac{1}{2}$ to $3\frac{3}{4}$ inches; not over 0.05% sulphur; not over 0.06% phosphorus if made by acid O-H process, and not over 0.04% phosphorus if made by basic O-H process. The required ultimate strength was 85000 lbs. per sq. in.; actual elastic limit, 48000; percentage of elongation in 18 ft., 9; percentage of reduction at fracture, 40. Among the advantages claimed for the eye-bar cables are: They offer better connections for the vertical suspenders; they are better adapted to form integral parts of the stiffening trusses to equalize moving loads on the bridge; and they can be proportioned economically with varying cross-section to the exact stresses in various parts of the cables, whereas wire cables must have a uniform cross-section. (For revised plans and specifications, see pages 756, etc.)

The parabolic curve may be used in making up preliminary estimates, and also for designing small suspension spans in general. See Fig. 3 and equations (1) to (8).

Example.—What will be the tension in each cable at top of tower, at mid span, and at quarter span, for a clear span of 600 ft., and a center deflection of 50 ft.; assuming total load at 8000 lbs. per lin. ft. of bridge, and supported by two cables?

Solution.—From the preceding equations:

At towers, each cable, equation (7), $t = \frac{1}{2} \cdot \frac{wl}{8d} \sqrt{h^2 + 16d^2} = 3,795,000$ lbs.

At mid span, each cable, equation (8), $t = \frac{1}{2} \cdot H = \frac{1}{2} \cdot \frac{wl^2}{8d} = 3,600,000$ lbs.

At quarter span, each cable, equa's (6)(3), $t = \frac{1}{2} \cdot H \sqrt{1 + \tan^2 \theta} = 3,650,000$ lbs.

Towers and Backstays.—Provision for expansion and contraction of the cables may be made at the towers in several ways:

(1) One of the most common methods is to sling the cables over the main piers on Saddles resting on a nest of rollers as in Fig. 7. Note in this

* Eye-bars not adopted; wire cable used in plans finally approved.

the load and the resultant reaction must necessarily be vertical, as the load eliminates any possibility of a horizontal component to the loading; also, the main cable and the backstay make an angle θ_1 with the horizontal, and are alike. Generally, any change in loading on main span will affect the angle of inclination

Fig. 7.

at top of towers, and in order that such angle may equal the angle of inclination of the main cable, the saddle moves automatically to restore equilibrium.

Truck, Fig. 8, gives the same movement as have the rollers *a* and *b*, in Fig. 7 the cable has double the movement. In Fig. 8, *h* represents the distance between the main cable and the backstay, *h* sec θ_1 , and *h* sec θ_2 . Vertical reaction at *a* is $h \tan \theta_1$, and vertical reaction at *b* is $h \tan \theta_2$; at the vertical reaction is directly proportional to the angle of inclination of cable.

Fig. 8.

Suspended Link (Fig. 9) suspended from *a*, and the Toggle (Fig. 10) supported at *b*, give the required lateral motion to the cable by temperature changes and moving loads. It is to be noted, however, in these cases that the reaction of loading on towers and the resultant reaction is not confined to the vertical as in the other cases, but take the direction of a line through pins *a* and *b*. The triangle of forces is the same in each case. The towers should be designed to take care of these loads for any direction in direction from the vertical, as well as the vertical loading itself.

Fig. 9.

Fig. 10.

Hinged Tower, Fig. 11, is simply an elongation of the cable. The cables may be fastened directly to the tower, and the latter being hinged at the bottom, the direction of the resultant load and reaction is in the same direction.

Fig. 11.

Backstay.—The maximum stress in the backstay, where the latter enters the ground, must be borne by the anchorage, with the proper safety. The anchorage proper consists of the backstays imbedded in masonry having sufficient weight or resistance to overcome the stress. For this purpose the backstays may be run in a straight line into the masonry or they may be run downward as in Fig. 12. The main backstay is attached at the point *a* may be composed of wire rope, and the anchorage chain below *a* may be composed of eye-bars in order to provide better connection with the anchors. In some cases the anchors are imbedded in solid concrete masonry, which insures permanent protection to the anchors. In other cases it has been deemed advisable to allow the anchorage to pass through open galleries so as to be accessible for inspection.

Fig. 12.

of anchorage for Budapest suspension bridge in *Eng. News*, Aug. 24, 1905; also, Fig. 17, page 759.

Cable Wrappings.—Fig. 13 shows the method of wrapping the cables for the

Fig. 13.

DETAILS OF MANHATTAN SUSPENSION BRIDGE.

Description.—Wire cable bridge of three spans: central span, 1470 ft.; two side spans, 725 ft. each. Four cables.

Cables.—About $20\frac{3}{4}$ " in dia., each consisting of 37 strands and containing 9472 parallel wires of 0.192 in. dia. before galvanizing, and not more than 0.197 in. dia. after galvanizing.

Fig. 14. Side Elevation of Bridge.

Live Loads.—(1) For the cables, trusses and towers: (a) a load of 8000 lbs. per lin. ft. of bridge as "regular," or (b) 16000 lbs. per lin. ft. of bridge as "congested" traffic. (2) For the hangers, floor beams and floor system: (c) on each elevated track a load of 52 tons on four axles, 6'-10'-6", the motor ends of cars of the Interborough R. T. Co.; (d) on each street car track either a load of 26 tons on 2 axles 10 ft. apart or a load of 1800 lbs. per lin. ft.

on any part of the roadway a load of 24 tons on two axles 10 ft. gage (assumed to occupy a width of 12 ft. and a length of 10 ft.) and upon the remaining portion of the floor a load of 100 lbs. per sq. ft. and on the footwalks a load of 100 lbs. per sq. ft.

pressure is assumed as a moving load acting in either direction with 2000 lbs. per lin. ft., but due allowance is made by lateral deflection into account.

ions for Material.—The wire for cables, hand ropes and suspensions have an ultimate strength of not less than 215,000 lbs. per sq. in. after galvanizing, and an elongation of not less than 2% in 12 ins. of length, the stretch to be measured while the specimen is in the line. The bright wire shall be capable of coiling cold around a diameter of its own diameter without sign of fracture. The serving wire shall be galvanized before galvanizing. After galvanizing, the steel wire shall have an ultimate strength of not less than 200,000 lbs. per sq. in. of

(Continued on next page.)

Fig. 15. Cross Section of Bridge.

Fig. 16. Details of Floor-Beam Connections.

The suspenders shall be $1\frac{1}{4}$ in. in dia. and weigh not less than 5.1 lbs. per lin. ft. They shall be composed of six strands of 19 wires each, laid around an independent wire rope center consisting of 49 wires, left hand lay. The suspenders shall be, preferably of long lay, but the lay must not be long enough to cause trouble in keeping the core in its true position during any of the operations before the suspenders are in their final position and loaded with the superstructure.

Economic Considerations.—The approximate costs of materials, erected, in a suspension bridge of about 1200 to 1500-ft. spans designed for combined railway and highway traffic, are as follows: Steel in wire cables, 6 to 6.25 cents per lb. (add about 4% to this for copper covering); riveted steel in center span, 4.25 to 4.5 cents per lb. (nickel steel, 6 to 6.25 cents); steel in towers, side spans and anchorage, 3.4 to 3.6 cents per lb.; steel in viaduct spans, about 3 cents per lb.; anchorage masonry, \$5.50 to \$6.50 per cu. yd.

Steel in *cantilever* spans, erected, about 4.5 cents per lb. (nickel steel, about 6 cents per lb.).

Machine for winding wire around main cables—Manhattan bridge	July 31, '09

44.—ARCHES.

General Discussion.—An arch is a structure so designed that the loading, including the weight of the structure itself, produces a thrust at the abutments, in such a manner that the resultant horizontal reactions at those points tend to relieve, wholly or in part, the bending-moment effect on the span.

The Ideal Arch would naturally take the (inverted) form which the cables of a suspension bridge assume for the particular conditions of loading imposed; for then the horizontal reactions at the abutments will relieve the arch ring of any bending moment whatsoever, the stresses throughout being purely of axial compression. Either of the curves described in Sec. 43, Suspension Bridges, if inverted, will become ideal arches for the *given* loadings. Such arches are called *linear* arches. The circular arch also is a linear arch when the resulting forces are radial, as in the case of a circular dam where the hydrostatic pressure is normal to the up-stream face.

The Circular Arch as a Dam.—Let r , Fig. 1, be the radius in feet of the up-stream face of the dam; h , the depth in feet below the surface of the water to the level at which the pressure is to be considered; p , the pressure in lbs. per sq. ft. at depth h ; W , the weight in lbs. of a cu. ft. of water. Then $p = Wh$; and the tangential compressive stress at any point of the circle for one foot vertical, and at depth h , is $T = pr = Whr = 62.5 hr$ lbs. = R . If t is the thickness of the masonry in feet at depth h , the compressive stress in lbs. per sq. ft. on the masonry is $\frac{T}{t} = 62.5 \frac{hr}{t}$. For overturning effect see Sec. 49, Dams.

Fig. 1.

The Catenary.—Let Fig. 1 represent a vertical arch of uniform thickness t and supporting its own weight only; then in order to be a true linear arch its curvature should be that of a catenary instead of a circle.

The Parabola.—Let Fig. 1 represent a vertical arch supporting, including weight of arch itself, a uniform *horizontal* load; then in order to be a true linear arch its curvature should be that of a parabola.

The Transformed-Catenary Arch.—Let it be required to design a masonry arch of 40 ft. span, 2 ft. in depth at the crown and 8 ft. at the springing line; and supporting a line load of 140 lbs. per sq. ft. Assuming the weight w of masonry at 140 lbs. per cu. ft., and the spandrel filling F to be solid at the same weight; and, further, reducing the live load to equivalent depth of masonry, namely, one foot, we have the outline diagram as shown in Fig. 2. The problem is to find the curve of the intrados (a transformed catenary) so that the line of resultant pressure shall trace the center line of the arch stones (practically) as shown by the middle dotted line. Note that the thinner the arch stones and the flatter the arch, the more nearly will this be true.

Fig. 2.

Solution.—First, find the value of m in the equation*

$$m = \frac{0.4342945 c}{\text{com log} \left(\frac{h}{a} + \sqrt{\frac{h^2}{a^2} - 1} \right)} = 11.34+; \text{ and substitute the values of } a(-2+1)$$

* See also the equation of the catenary and transformed catenary in Sec. 43, Suspension Bridges.

and m in the general equation $*y = \frac{a}{2} \left(e^{\frac{x}{m}} + e^{-\frac{x}{m}} \right) - \frac{3}{2} \left(e^{\frac{x}{m}} + \frac{1}{e^{\frac{x}{m}}} \right)$. Then:

For	$x =$	0.	5.	10.	15.	20.
	$y =$	3.00	3.30	4.24	6.03	9.00
Depth of masonry	$=$	2.00	2.30	3.24	5.03	8.00

The above calculation is very simple, requiring only a few minutes' time, remembering that $\log e^{\frac{x}{m}} = \frac{1}{m} \log e$, $= 0.4342945 + 11.34 = 0.03828$ for this particular case; and $\log e^{-\frac{x}{m}} = 0.03828 x$. Also note that $e^{-\frac{x}{m}}$ is the reciprocal of $e^{\frac{x}{m}}$ and hence $\log e^{-\frac{x}{m}} = 1 - \log e^{\frac{x}{m}}$.

The Horizontal Thrust H at any point of the arch for each foot in length (perpendicular to face) is $H = wm^2 = 140 \times (11.34)^2 = 18\,000$ lbs.; and at crown of arch = 9000 lbs. per sq. ft. = 62.5 lbs. per sq. in.

The Vertical Shear P_x , at any point distant x from the center of arch, is $P_x = \frac{H}{m} \sqrt{y^2 - a^2} = wm \sqrt{y^2 - a^2}$; and at the abutment the shear is equal to the vertical reaction $P = \frac{H}{m} \sqrt{h^2 - a^2} = wm \sqrt{h^2 - a^2} = 140 \times 11.34 \times \sqrt{81 - 9} = 13471$ lbs.—per lin. ft. (axial) of bridge.

The Area $\frac{A}{2}$ of Half the catenary, between directrix and soffit, is $\frac{A}{2} = m \sqrt{h^2 - a^2} - \frac{P}{w} = \frac{13471}{140} = 96.22$ sq. ft.

The area of face of masonry = $96.22 - 20 = 76.22$ sq. ft.

The depth of arch stones is assumed to be 24 inches, but with a uniform live load as above it may safely be much less. The tangential thrust at the springing line is equal to $\sqrt{H^2 + P^2} = 22482$ lbs. or only 78 lbs. per sq. in. The tangent of the angle which this thrust makes with the horizontal at that point is $\tan \theta_1 = \frac{1}{m} \sqrt{h^2 - a^2} = \frac{P}{H} = 0.7484$; therefore $\theta_1 = 36^\circ - 49'$, the thrust being tangent to the soffit of the arch. At any point distant x from center of span, $\tan \theta = \frac{1}{m} \sqrt{y^2 - a^2}$. With a variable live load on the arch the resultant line of pressure through the middle of the arch stones will change its form and deviate from a true central position. The amount of deviation in the present instance cannot be more than $\frac{1}{2} \times \frac{24}{3} = 4$ inches, or one-half the "middle third," without producing tension in the masonry joints, which is not allowable. (See Masonry Arches, following.)

The live load on the span is assumed at 140 lbs. per sq. ft. of floor, equivalent to a depth of one foot of masonry. Now it is plainly evident that the curve of the intrados of the arch (Fig. 2) will not be affected by any relative change of live load to dead load provided the "loading contour" remains the same. Thus, we may increase the uniform live load to 280 lbs. per sq. ft. by decreasing the depth of masonry one foot, making the depth of arch stones 12 ins. instead of 24 inches. This, of course, would double the thrust on the arch stones per sq. in., making the horizontal thrust at crown 125 lbs. per sq. in., and the tangential thrust at springing 156 lbs. per sq. in. The line of resultant pressure would not change its form but would now conform more nearly with the (new) middle line of the arch stones. They will never exactly coincide unless the arch ring is reduced to a thin plate.

The resultant line of pressure as previously determined will evidently be affected by changes in the loading contour: (1) By raising the loading contour, that is, increasing the uniform load per sq. ft.; (2) by lowering the loading contour, that is, decreasing the uniform load; (3) by considering the uniform load at middle of span only; (4) by considering the uniform

* $\log e = 0.4342945$.

Tudor arch, modified Gothic with intrados compounded. The "four-centered" Tudor arch is shown in Fig. 5. The radii are $\frac{1}{2}$ and $1\frac{1}{2}$ of the span, respectively. **Elliptical arch**, intrados is part of an ellipse. The major axis may be either horizontal or vertical. (Any arch is said to be *surbased* when the rise is less than the half-span; and *surmounted* when the rise is greater than the half-span.) **Oval** or "basket-handle" arch, intrados composed of arcs or circles approaching the elliptic arc in form. The "three-centered" oval is very common. **Parabolic arch**, intrados is parabolic. **Catenarian arch**, intrados is catenarian.

Further Classification of Arches.—**Right arch**, one whose ends or faces are perpendicular to axis of arch. **Skew arch**, an arch whose ends or faces are oblique to axis of arch. There are two kinds:

Fig. 6.

Fig. 7.

or arches cross each other. **Dome**, formed by right section of arch revolving around vertical axis through center of keystone. (Also, see Glossary.)

Brick Arches.—The three principal methods of bonding brick arches are illustrated in Fig. 8, and described as follows:

Rowlock bond (R).—All the bricks are laid as stretchers in concentric rings. The average thickness of joint is less under this construction, and hence more bricks and less mortar are required. It is cheaper to lay, and is employed largely in tunnel work, sewers, etc., where architectural effect is not important.

Header and Stretcher bond (H. & S.).—Radial joints continuous, and bricks laid as headers and stretchers. The average thickness of joint is greater under this method, and hence more mortar and less (the least) number of bricks are required. It is more pleasing to the eye than the rowlock bond, and is used largely in the fronts of buildings.

Block in Course bond (B. in C.).—This bond aims to attain with brick the wedge-shaped voussoirs of the stone arch. That is, the bricks are grouped in sections bounded by continuous radial joints. Adjacent sections are of different bond, any good bond being permissible. Bonds with continuous radial joint are usually made narrower than those bonds where radial joints are broken.

Fig. 8.

The Masonry Arch Is a Statically Indeterminate Structure, and its solution is based on various assumptions more or less approximate. These will be considered in the material order of design. To begin with, we have to assume the finished arch and then examine it for stability (resistance to deformation), strength (resistance to crushing), economy, etc.

Curve of Intrados.—The form of curve selected for the intrados will naturally affect the thickness of the arch ring and the economy of the whole structure. We have seen (Fig. 2) that the transformed catenary is the ideal curve of soffit where the loading contour is a horizontal line, and this curve would undoubtedly be used were the conditions of loading constant as shown. It will be noted that in the transformed catenary the curve is quite flat at the crown and gradually becomes sharper toward the springing. The ellipse is a curve that can be made to approximate the modified catenary.

mple than the latter. It may be used in the form of the semi-ellipse*. If the latter is used the major axis be of the arch, and the semi-minor axis the rise. One of the arches in the world is the ("New") London bridge over the and, for street traffic. It is a granite arch of 152 ft. span, and with a crown radius of 162 ft. The thickness at crown is springing, 9.00 ft. The *basket-handle* or *many-centered arc* is of the ellipse, and has certain apparent advantages over an applied to an arch of cut stone. To this class belongs constructed stone arch bridge at Plauen, Saxony, with a 195.2 ft., the longest ever built. The total rise is 59 ft., and of arch stones at crown is 4.92 ft. It is 5-centered, with 191.8 ft., and 101.7 ft. The *circular* form, using the arc most frequently employed on account of its simplicity, in om, for the stone cutter, and in laying out the centers for field. The "*segmental*"† arch subtends a central angle at inly employed in building construction. The *semi-circular* a central angle of 180° and is particularly adapted to ough high embankments where the rise of the arch is and where the haunches of the arch are called upon ined forces due to earth pressure. The largest semi-own to the writer is the Ballochmyle, over the Ayre, Scotland. arch of 181 ft. span. The thickness of ring at crown is 4.5 ft., ng 6 ft. The *parabola* is sometimes used for flat, concrete ot particularly economical for a masonry arch because of the the loads; that is, a parabola would call for a uniformly d over the structure, whereas in a masonry arch this condi- be approximated. In *conclusion*, we may state that, king, the basket-handle is doubtless the best form to use for cut-stone work — 5-centered for extremely long spans, and medium long spans, say up to 200 feet. For concrete arches may be used for any length of span; the semi-ellipse, for any where the rise is considerable; also for short spans in general; e, for moderate and short spans, especially of cut-stone.

ublic Oval is a new arch curve designed by Chas. Worthington, E., and is described very elaborately in *Eng. News* of April anied by numerous illustrations.

of Arch Ring.—Theoretically, the arch stones should have ss at the springing than at the crown, because of the greater ust. For practical reasons, however, the thickness of the ually made uniform throughout for spans up to 75 ft. For an than 75 ft. the thickness at springing is usually from 25 to eater than at crown‡, depending upon length of span, rise, etc.

ssuming thickness of arch stones.—Having selected the most e for the intrados the next step is to approximate as closely e thickness of the arch ring at crown and at springing. No

s of curvature r for any point p (whose coordi- a and y) of the ellipse, whose semi-major axis is a , b or axis b (Fig. 9), is

. For the semi-ellipse where b = the rise, and

the radius of curvature at crown C is (for Fig. 9.

$$\frac{a^2}{b} = \frac{(\text{half span})^2}{\text{rise}}; \text{ and the radius of curvature at springing } (x=a), r = \frac{b^2}{a} = \frac{(\text{rise})^2}{\text{half span}}.$$

a "*segmental*" is here used in its restricted meaning; but in se any circular arch is a segmental arch.

e exception to this rule is the railway arch bridge of 4 spans ow river, England. The spans are each 100 ft.; rise, 25 ft.; ickness of ring, 4 ft. Such a depth at crown, however, is exces-

absolute, simple rules can be devised, but the writer presents the following as giving very close results for first-class concrete and cut stone work:

Thickness t , at crown (all dimensions in feet):

$$\text{For highway bridges } t \text{ at crown} = \sqrt{0.01 \text{ span} \left(\frac{\text{span}}{\text{rise}} + 3 \right)} + 0.15 \dots (1)$$

$$\text{For high H. W. em-} \left. \begin{array}{l} \text{bankments, or} \\ \text{For railroad bridges} \end{array} \right\} t \text{ at crown} = \sqrt{0.01 \text{ span} \left(\frac{\text{span}}{\text{rise}} + 4 \right)} + 0.20 \dots (2)$$

$$\text{For high R. R. em-} \left. \begin{array}{l} \text{bankments,} \end{array} \right\} t \text{ at crown} = \sqrt{0.01 \text{ span} \left(\frac{\text{span}}{\text{rise}} + 5 \right)} + 0.25 \dots (3)$$

Thickness t , at springing (all dimensions in feet):

$$\text{For all cases, } t \text{ at springing} = t [1 + 0.002(\text{span} + 2 \times \text{rise})] \dots (4)$$

1.—CROWN THICKNESS t , (FEET) FOR MASONRY ARCHES.

[Calculated from Formulas (1), (2) and (3).]

Remarks.—The above table is for solid arch rings. Where arch rings are ribbed the thickness or depth of ribs should be increased. For spans under 75 ft. an arch ring of uniform thickness may be used by increasing the crown thickness obtained from above table by from 5 to 20%. See Table 2.

Tables 5 and 6, pages 774 to 781, contain various data from arches that have been built.

2.—TABLE FOR OBTAINING THICKNESS t OF ARCH STONES AT SPRINGING.

Values of $[1 + 0.002 (\text{span} + 2 \times \text{rise})]$ in Equation (4).

Thickness at springing = thickness at crown $\times$ tabular values below.)

Rise + Span.		Span, in Feet.						Rise + Span.		Span, in Feet.					
Frac.	Dec.	75	100	150	200	250	300	Frac.	Dec.	75	100	150	200	250	300
1-10	.10	1.18	1.24	1.36	1.48	1.60	1.72	1-5	.20	1.21	1.28	1.42	1.56	1.70	1.84
1-8	.125	1.19	1.25	1.38	1.50	1.63	1.75	1-4	.25	1.23	1.30	1.45	1.60	1.75	1.90
1-7	.143	1.19	1.26	1.39	1.51	1.64	1.77	1-3	.333	1.25	1.33	1.50	1.66	1.83	2.00
1-6	.15	1.20	1.26	1.39	1.52	1.65	1.78	1-2	.40	1.27	1.36	1.54	1.72	1.90	2.08
1-6	.167	1.20	1.27	1.40	1.53	1.67	1.80	1-2	.50	1.30	1.40	1.60	1.80	2.00	2.20

Note from Tables 1 and 2 that for any given span the actual thickness of arch ring at springing remains nearly constant as the rise approaches the half span.

Problem.—In designing a railroad masonry arch of 200 ft. span and 40 ft. rise, what thickness of arch ring shall be assumed, tentatively, at crown? Also at springing?

Solution.—At crown, 4.44 ft. (from Table 1). At springing, 4.44×1.56 (from Table 2) = 6.93 ft. Hence use 4.5 and 7, respectively, for trial.

Forces Acting on a Masonry Arch.—These may be classified as the "outer" and the "inner" forces, the same as in any other structure. The outer forces include (1) the moving loads due to trains, vehicles, etc.; (2) the mixed loads, due to weight of track, roadway, embankment, spandrel filling, etc.; (3) the dead loads due to weight of arch ring itself; (4) the reactions. The inner forces comprise the stresses in the arch ring, usually calculated at points of imaginary joints. These stresses are examined for compression, shear, and possible tension. The compression is determined from the line of resultant pressure through the arch ring, which also reveals possible tension. The shear at any point of the arch is equal to the algebraic sum of the outer forces at the left of that point, taken in the direction of the cutting plane. Furthermore, we know that the algebraic sum of the outer forces, either of the whole structure or of that portion at the left of any given cutting plane, is equal to zero. The same is true of the inner forces; also of the outer and inner forces combined. Hence, an inner force in a complete structure may be determined by assuming it to be an outer force in maintaining equilibrium in a portion of the structure.

Direction of Outer Forces.—Let Fig. 10 represent a masonry arch with arch ring drawn to scale. Let MM represent the mixed static loading above the arch ring due to spandrel filling, roadway and track, and with depth reduced to equivalent masonry loading, so that d , in feet, at any point distant x from left abutment, will represent the intensity of the total static loading at that point in terms of the weight of masonry per cubic foot. If, now, we add the moving load m for any particular case of loading, say on the right half of span, and reduce the same to equivalent depth of masonry, we obtain the loading contour for calculating the arch for that particular case of loading.

Fig. 10.

Vertical Loading.—In fixing the loading contour as above we have assumed all loading to be vertical, which, although not quite correct, is the usual assumption. Note that the line of resultant pressure (dotted) through the arch ring approaches the upper edge on the more heavily loaded half, and the lower edge on the less heavily loaded half, indicating a tendency to cause tension in joints at t , which must be guarded against, as well as undue compression at c . The thrust T at crown will not be horizontal but will incline upward to the right because of the heavier loading on that side,

producing positive vertical shear V at crown. The horizontal component H of thrust T is, $H = \sqrt{T^2 - V^2}$ = horizontal component of R_1 or of R_2 , also.

Inclined Loading.—The loading at the crown may always be assumed as vertical; also at the haunches if the spandril filling is of rough masonry, or of earth or clay well tamped and kept thoroughly drained. But if the filling is of loose earth, sand or gravel, and especially if liable to become saturated with rain, from poor drainage, the material will have a tendency to slide along a low angle of repose, with resultant inclined loading at the haunches, as *FFF*, Fig. 10. Such inclined loading will produce a different line of resultant pressure in the arch ring than will vertical loading.

Three-Hinged Masonry Arch.—(The following theories are approximate only.) The three hinges, *a f k* (Fig. 11), placed at crown and at springing, are necessarily points of zero moment and hence the line of resultant pressure must pass through those points. The method of procedure is as follows: Divide the arch ring into imaginary voussoirs with radial joints. From the upper extremities of these joints draw vertical lines up to the loading contour *L. C.* Find the area and the center of gravity of each of these figures, bounded by full lines, between the *L. C.* and the soffit of arch.

Then the area multiplied by the weight of the masonry per cu. ft. will give the vertical loads P_1, P_2, P_3 , etc., passing through the centers of gravity of the figures. The reactions R_1 and R_2 , as well as their horizontal and vertical components, may be found graphically (see Fig. 17, Sec. 16, page 315) by treating each load separately or by using one or more resultant loads. With H, V_1, V_2 , and the loads P_1, P_2 , etc., the force polygon (Fig. 12) may be constructed, and the equilibrium polygon shown in Fig. 11 may be drawn; thus, draw R_1 through *a*, parallel to R_1 of the force polygon, to meet P_1 produced; from this intersection draw $1'$ parallel to 1 to meet P_2 produced, etc. If the work is done carefully the equilibrium polygon will pass through the hinges *f* and *k*. See also Fig. 14.

The Line of Resistance or line of resultant pressure (not shown in Fig. 11) may be drawn by connecting the points *a b c d—f—k* where the chords of the equilibrium polygon, as shown, intersect the masonry joints. But it must be remembered that if, in the equilibrium polygon, any point as *p* due to a load as P' falls outside the area from which the loading is derived, then the chords of the equilibrium polygon must be produced to meet the joint and give position to points on the line of resistance. Thus, in Fig. 13 the line of resistance will pass through *b'c* instead of through *bc*.

It is to be noted that the pressure at each of the joints may be obtained by scaling the rays of the force polygon, using the proper scale; thus, the pressure at *c*, intersected by $2'$ (Fig. 11), is obtained by scaling ray 2; *d*, by scaling ray 3; *f*, by scaling ray 5. The force polygon also gives the vertical shear V at crown. As the loading is all vertical the value of H (horizontal thrust) is constant throughout the arch.

Three-hinged masonry arches are usually constructed of concrete or reinforced concrete. The hinges, at crown and springing, usually consist of steel shoes with pin bearings; sometimes lead sheets are used.

The Criterion of Stability of a masonry arch is whether the true line of resistance for any case of assumed loading lies wholly within the middle third. If it does, the arch is stable for that loading. Now, while we can draw practically a true line of resistance for an arch with three hinges (Fig. 11), it is impossible to draw a true line of resistance for an ordinary arch with no hinges, and in order to determine its stability we have to make certain assumptions.

Ordinary Masonry Arch—No Hinges.—Dr. Winklers' theory for the line of resistance of an arch is as follows: "For an arch of constant cross-section, that line of resistance is approximately the true one which lies nearest to the axis of the arch ring, as determined by the method of least squares." Hence, for all practical purposes, if a line of resistance can be drawn within any portion of the arch ring, say the middle third, the true line of resistance

Fig. 11.

Fig. 12.

Fig. 13.

that portion.* Furthermore, in the clear language of Prof. Arch and its load being given, a line of resistance can always be drawn through any *two* given points; hence, if any two points of resistance are given, the line is determined." In practice, we select two points within the portion of the arch ring, say the middle third, and draw a line of resistance passing through them. If this line of resistance lies within the portion of the ring, the arch is stable; if not, another line is selected (one of which may remain unchanged) and another line of resistance is drawn, etc., until it is determined whether a line of resistance can be drawn within the given portion of the arch ring. If such a line can be drawn, the thickness of such ring is increased, or the arch is modified, or both.

Unsymmetrical Loading.—Let Fig. 14 represent one half of a symmetrically loaded arch. P_1, P_2, P_3, P_4 and P_5 , the loads on that half, and R , the resultant of those loads. It is to be determined whether the arch is stable with the line of resistance within the middle third, which is bounded by the two points a and b , the former at the springing and the latter at the upper edge, of the middle third; and pass a line of resistance through the two points. The thrust H at b must be horizontal and the line of resistance symmetrical in form and loading, and the thrust H must be determined by taking moments

Fig. 14.

$Hh = Pd$, or $H = P \frac{d}{h}$. Now draw the force

H , laying off the value of H thus obtained, from the foot of the load line, to the point O ; and draw the line of resistance, say $R, 1, 2, 3$, etc. Now draw the equilibrium polygon, dotted in Fig. 14: producing H to P_5 ; then draw a line parallel to ray 4, to P_4 ; 5' parallel to 5; etc. The line of resistance (not shown) will be at the intersection of the chords of the equilibrium polygon, thus found, with the line of resistance.

Fig. 15.

and by inspection we see that the line of resistance, if it lies outside the middle third of the first three joints to the left of the crown, does not prove that the arch is unstable, for, by selecting b_1 instead of b , and readily obtain a line of resistance within the middle third and passing through a and b_1 . The new line of resistance will have the pole O_1 instead of O , and distant H_1 horizontally from the load line, the value of H_1 being equal to $P \frac{d}{h_1}$. A mere

comparison will indicate that the *true* line of resistance, although it is not determined definitely, will lie nearer the axis of the arch and the springing and crown joints well within the middle third instead of as indicated by points a and b_1 .

Symmetrical Loading.—If we analyze the preceding case of symmetrical loading, critically, we cannot fail to see that we have really assumed the arch, of which Fig. 14 represents one-half, to be 3-hinged—one hinge at the crown and one at each springing; that we have taken the line of resistance to be at any part of the joint within the middle third of the ring; and that, because of the symmetry, it is unnecessary to consider one-half the arch only.

The case of unsymmetrical loading calls for but little special consideration when viewed from the above standpoint. Fig. 16 be the arch under consideration, and P_{10} derived from a loading contour (see Fig. 1). Assume three points within the middle third of the ring to act as hinges. Then draw a 3-hinged arch, and calculate the arch by the method which will give a line of resistance passing through the three selected points, and the line of resistance lies wholly within

Fig. 16.

as he himself claims that this is not strictly true, but it is as nearly true as the authorities noted.

In a 3-hinged arch, three points are given because they are the only points where the moment is absolutely determined.

the selected middle portion of the arch ring the arch is considered stable; if not, select three points again until, by repeated trial, it is determined whether or not the arch is stable, as explained for Fig. 14. Two methods will be shown for drawing the equilibrium polygon, from which the line of resistance is determined.

First Method.—Time will be saved by a proper selection of points to be assumed for the hinges. In Fig. 16 where the heavier loading is on the right half of span the hinge c on that end is assumed at the inner edge of the middle portion; on the left end, carrying the lighter load, the hinge a is assumed at the outer edge of the middle portion; while at center of span the hinge b is assumed at the middle of the vertical joint. Draw the equilibrium polygon passing through those points, $a b c$, treating the arch as 3-hinged, as explained for Fig. 11. Examine for stability.

Fig. 17.

Second Method.—Select the hinges as above (Fig. 16). Lay off the load line in the force polygon, Fig. 17. Choose any pole as O , and draw the rays (dotted) of the force polygon. Construct the equilibrium polygon (dotted) in Fig. 16, beginning at c and ending at a' . Draw the trial closing line $a'c$. Draw OM (Fig. 17) parallel to $a'c$ to meet the load line at M . From M draw MO_1 parallel to the true closing line ca . Make the distance $MO_1 = k \frac{d}{d_1}$.

in which k = the horizontal distance to the load line. Then will point O_1 be the true pole of the force polygon. Draw the rays (full) from O_1 , and construct the equilibrium polygon (full) in Fig. 16, beginning at c . It will be found that the chords will pass through the hinges b and a . Examine for stability. If unstable select new points for hinges, and proceed as before.

The "middle third" of the arch ring is usually selected as the "middle portion" within which to draw the line of resistance because, theoretically, when the line of resistance passes within the middle third there can be no tension in any part of the masonry, nor opening of any of the joints. If the arch ring is stiffened greatly by solid spandril walls the criterion of stability may not require that the line of resistance be confined within the middle third, but, say, within the middle half.

The cases of loading for an arch are: (1) dead load only; (2) full load, including live load over whole span; (3) including live load over one-half of span; (4) including live load in any position; (5) including concentrated loads. It must not be presumed however that for all these cases of loading it is necessary to assume the hinges in any one fixed position.

Centers for Arches.

Definition.—An arch center is a framework for supporting an arch during construction, and hence of temporary character. It is so designed that it can be removed readily after the completion of the arch; and in the removal it has to be lowered somewhat in order to give sufficient clearance at the soffit of the arch, as the latter settles and becomes self-supporting.

Parts of the Arch Center.—Fig. 18 shows two half-sections of arch centers with an end view of one of the frames. One half-section illustrates

Fig. 18.

the unbraced rib which supports the sheeting or lagging on which the arch stones are laid. The other half-section is a trussed frame, suitable for long

spans. When trussed, the rib is called the *back piece*. The truss shown in Fig. 18 is the King post, the inclined *braces* transmitting the stresses from the haunches directly to the vertical post, and then down the inclined *struts* to ends of span. Various forms of trusses are used for the frames, depending upon length of span, rise, etc. The frames are placed perpendicular to the axis, spaced in parallel planes, and supported by *wedges* which are "struck" when the center is removed. Instead of the wedges, *jacks* or *sand cylinders* can be used for this purpose.

Loads.—The loads which an arch center has to support are:

Live loads, including (1) The percentage of weight of placed masonry supported, in different sections of the arch; (2) Same with regard to unplaced masonry and other materials, machines, derricks, men, etc.; (3) Impact due to handling material during construction of arch.

Dead loads, comprising weight of center itself, including sheeting, frames, trestling, etc.

Calculation of live loads.—Three cases will be considered, as noted above:

(1) *Masonry in place.*—In Fig. 19 let the shaded portion show the voussoir *V* or section of masonry whose weight is *W*. Then:

(a) If we assume *V* as merely resting without friction on the joint *J* and on the back of the arch center, we have, letting β equal the angle of inclination of the normal pressure *W_n* with the horizontal,

$$W_n = W \sin \beta \dots\dots\dots (1)$$

and the vertical and horizontal components of *W_n* are $W_v = W \sin^2 \beta$, and $W_h = W \sin \beta \cos \beta$, respectively. $W_t (= W \cos \beta)$ is the tangential thrust. It is worthy of note that the normal pressure *W_n* of equation (1) would equal *W* for any voussoir at the crown *c*, and zero for any voussoir at the hor. springing *s*. Authorities differ, however, as to the value of the equation for sections between these two points, on account of the unknown effects of friction, which latter would tend to reduce the value of *W_n*.

Fig. 19.

(b) If we assume the voussoir *V* as hinged at *o*, then, by taking moments,

$$W \cdot h = W_n' \cdot d, \text{ or } W_n' = W \frac{h}{d} \dots\dots\dots (2)$$

Now *W_n'* of equation (2) will equal *W_n* of equation (1) only when the voussoir *V* is extremely thin, practically a plate, and when its intrados is a straight line instead of a curve as shown in Fig. 19. Otherwise its value will be less than *W_n* of equation (1).

(c) If we assume friction at the joint *J* we have, calling α the angle which the joint makes with the horizontal, and θ the angle of repose of the masonry,

$$\text{Normal pressure } W_n'' = W_n - W \tan \theta \cos \alpha, \text{ nearly} \dots\dots\dots (3)$$

$$\text{or } W_n'' = W_n' - W \tan \theta \cos \alpha, \text{ nearly} \dots\dots\dots (4)$$

in which $\tan \theta$ may vary from 0.50 to 0.65; that is, the angle of repose θ may vary between, say, 27° to 33° . The problem becomes more difficult if we attempt to include the friction of the soffit of *V* on the back of the arch center.

(2) *Unplaced masonry, machines, etc.*—These would tend to increase the stresses and must be allowed for liberally, especially over the haunches where the stresses are particularly indeterminate.

(3) *Impact.*—The amount of impact would depend largely on the size of the stones used; it can be taken into account in a general way, if small, by the "factor of safety" adopted.

Practical formula for live loads.—Let *W* = weight of section or voussoir *V* (Fig. 19), *W_n* = normal pressure due to *W*; and β = angle of *W_n* with the horizontal. Then

$$W_n = W \sin^2 \beta \dots\dots\dots (5)$$

3.—VALUES OF W_N FOR SUCCESSIVE VALUES OF β .From $\beta = 90^\circ$ (at crown) to $\beta = 0^\circ$. Equation (5).

Angle β .	Normal Pressure W_N .	Angle β .	Normal Pressure W_N .	Angle β .	Normal Pressure W_N .	Angle β .	Normal Pressure W_N .
90°	1.000 W	70°	0.830 W	50°	0.450 W	30°	0.125 W
88°	.998 "	68°	.797 "	48°	.410 "	28°	.103 "
86°	.993 "	66°	.762 "	46°	.372 "	26°	.084 "
84°	.984 "	64°	.726 "	44°	.335 "	24°	.067 "
82°	.970 "	62°	.688 "	42°	.300 "	22°	.053 "
80°	.955 "	60°	.650 "	40°	.266 "	20°	.040 "
78°	.936 "	58°	.610 "	38°	.233 "	15°	.017 "
76°	.914 "	56°	.570 "	36°	.203 "	10°	.005 "
74°	.888 "	54°	.530 "	34°	.175 "	5°	.001 "
72°	.860 "	52°	.489 "	32°	.149 "	0°	.000 "

Use of Table: Example.—A section of arch masonry weighing 20 tons is supported radially by a brace of the arch center acting normal to the intrados and making an angle $\beta = 50^\circ$ with the horizontal. Find the compressive stress on the brace due to this load?

Solution: W_N for $\beta = 50^\circ$ is 0.45 $W = 9$ tons. Ans.

Types of arch centers.—Fig. 20 illustrates the most simple form of centering, that for a flat-soffit arch. The illustration is that of a Flat Arch of the recessed type. They are built up to 8 or 10 ft. in span.

Fig. 20.

Fig. 21.

The caps supporting the lagging rest on longitudinal stringers, which are in turn supported by posts. Note the economy of material in lagging by increasing the depth of strips at the expense of width. The strength is proportional to width and to (depth)².

Fig. 21 is the standard segmental arch used over doors and windows. The "back" of the center consists of templates of thick boards cleated together. The lagging is spaced closer together if the arch is of brick. Note that the points $o a a$ form an equilateral triangle in both Figs. 20 and 21.

Fig. 22 shows the make-up of braced or unbraced wooden rib as illustrated in Fig. 18. The segmental pieces are sawed from plank and (nailed or) bolted together into two or more leaves according to the strength desired. The ribs should, preferably, be braced, although unbraced ribs have been used up to 50 or 60 ft. spans.

Fig. 22.

Fig. 23 represents the leaves of the rib laid flat-wise instead of vertical as in the preceding case. This type is the same as that used in chords of ordinary wooden bowstring truss bridges.

Iron or steel ribs are sometimes used instead of wooden ribs in cases where great strength and stiffness are required. I-beams are the best for this purpose.

Fig. 23.

Fig. 24 illustrates a supported trussed frame, mainly of the Warren type. The left half-section is shown supported by vertical posts. The right half-section is shown supported by inclined posts, which system is

Fig. 24.

Fig. 25.

sometimes adopted for economy, as in the case of swift currents or ice. The same type may also be used without interior supports. In fact the end supports may also be omitted by allowing the ends of frames to rest on projections or in (artificial) recesses of the abutments.

Fig. 25 is a skeleton outline of center used in the erection of 60-ft. arch of Washington bridge,* New York City. The sand cylinders *s*, are used instead of wedges or jacks for lowering the center after the arch is completed. They consist of 12-in. plate-iron cylinders filled with sand on which rests the plunger, which forms a support to the centering above. By manipulating a plug at the bottom of the cylinder the outflow of sand is regulated and consequently the lowering of the center. In using sand cylinders under centers, care must be used to keep the sand perfectly dry. They have met with varying success.

In Table 6, next to last column, reference is made to the files of *Eng. News*, by date, of descriptions of some recently constructed arches. Many of these descriptions embody the designs of the centers quite as much as of the masonry.

Striking the center.—This consists in lowering the center for removal after the masonry arch is completed, either by striking the wedges, operating the jacks or manipulating the sand-boxes to relieve the pressure at the soffit.

The time when this should be done will depend upon the length of span; size and kind of voussoirs, whether brick or stone; character of bond; character and thickness of joint; quality of mortar, etc. For instance, there could be little objection to striking the center almost *immediately* of a first-class stone arch bridge of moderate span with large voussoirs, well bonded, with close-fitting joints. On the other hand, it would be unwise to do so in the case of a brick arch of long span, small rise, thick joints, and bricks poorly bonded, as considerable unhealthy deformation might take place. Again, in the case of arches in building walls, considerable time should elapse before the centers are removed, at least until the bricklaying above the arch is beyond its sphere of influence in causing additional weight or pressure. Three or four months is the outer limit for any case, as that gives ample time for hardening of the mortar. The presence of the centering need in no way interfere with the traffic over the structure.

Camber of center.—In laying out and erecting the center of an arch, it is sometimes advisable to give the frames a slight camber, amounting, at the crown, to about $\frac{1}{4}$ or $\frac{1}{2}$ per cent. of the *radius* of the intrados. Of course the object of this camber is to provide for all settlement so that the intrados of the finished masonry structure shall be the true curve as designed, and on which the calculations of the structure are based.

The total camber to be provided for will equal (1) the deflection of frame due to its own dead weight; (2) the deflection due to weight of masonry of completed arch; (3) settlement when center is removed; (4) further settlement due to superimposed loads on arch.

If the center is rigidly constructed, the arch stones well laid with close joints, and the arch itself not of the pronounced "flat" type, very little, if any, camber is required.

Tables of Arches.

Table 5, following, is a list of some notable arches that have been built, with principal dimensions and important remarks.

Table 6 comprises some typical modern arches. Reference is given to the files of *Engineering News*, where fuller descriptions are given.

5.—SOME NOTABLE ARCHES THAT HAVE BEEN BUILT.

Note.—*Ris*=rise; *Rad*=radius at crown; *Cr*=thickness of ring at crown; *Sp*=thickness at springing; all dimensions in feet and decimals. *Rein.-conc.*=reinforced concrete; *3-cen.*=3-centered, etc.

No.	Span.	(Dimensions.)	Name and "Kind." [Engineer and Date.]	Remarks.
1*	295.27	(<i>Ris</i> =60±, <i>Rad</i> =344.48, <i>Cr</i> =4.92, <i>Sp</i> =11.15).	<i>Plauen</i> , Saxony. "Stone; 3-cen." [1905.]	Flattest stone arch ever built, and longest span. Solid arch (without hinges). Arched abutments rise from solid rock foundation so that static (elastic) arch proper has span of 213.2 and rise of 21.2 ft. Live loads: (1) A 15-ton vehicle 9.84 ft. bet. axles and a unif. load of 114.6 lbs. per sq. ft.; (2) 8 steel rollers total weight 25.16 tons and a unif. load of 114.6 lbs. per sq. ft. Calc'd pressure, including temp., was 981.4 lbs. per sq. in. on top edges of joints at crown, and 745.1 lbs. on lower edges of joints. Max. pres. on foundations 355.6 lbs. per sq. in., the foundation rock having crushing strength of 23760 lbs. per sq. in. Mortar for foundations, 1 Portland cement to 4 sand for main and secondary arch, 1 Port. cem. to 3 sand. Large spandrel openings.
2*	275.6	(<i>Ris</i> =100±, <i>Rad</i> =, <i>Cr</i> =, <i>Sp</i> =).	<i>Luxemburg</i> . "Stone, -cen." [1901.]	
3	251.	(<i>Ris</i> =88, <i>Rad</i> =133, <i>Cr</i> =4).	<i>Trezzo</i> , over Adda, Italy. "Granite; circ." [Built, 1380; destroyed intentionally, 1420 ±.]	
4*	233.	(<i>Ris</i> =70.25, <i>Rad</i> =118.75, <i>Cr</i> =5.5, <i>Sp</i> =9.5).	<i>Walnut Lane</i> , Phila. "Concrete, 3-centered." [Webster, 1907.]	Twin arch rings. Spandrel arches; and arch approaches. Actual deflection on removing centers was $\frac{1}{4}$ in. at crown and 1-32 in. at quarter points, the calculated deflection at crown being $\frac{1}{4}$ in., the difference being accounted for partly to rise in temp.
5	220.	(<i>Ris</i> =57, <i>Rad</i> =134, <i>Cr</i> =4.2+4, <i>Sp</i> =6+15).	<i>Cabin John</i> , Washington, D. C., aqueduct. "Stone, circ." [Meigs, 1853-9.]	The voussoirs of the arch ring are of Quincy granite making depth at crown 4.2 ft., and thickness at springing 6 ft. The spandrel filling of sandstone is laid partly with radial joints so as to increase effective depth of ring to 8.2 ft. at crown and 21 ft. at springing. The arch carries a 20-ft. roadway and a 9-ft. conduit.
6	213.	(<i>Ris</i> =59.6, <i>Cr</i> =6.9, <i>Sp</i> =10.2).	<i>Jaremcse</i> , Austria. "Circ." [1892.]	Spandrel openings. Railroad.
7*	211.5	(<i>Ris</i> =87.6, <i>Rad</i> =89.25, <i>Cr</i> =4.33, <i>Sp</i> =6.5).	<i>Kempton</i> , Bavaria. "Concrete; basket-handle." [1907.]	4-track railroad. Twin arch rings.
8*	210.	(<i>Ris</i> =52.5).	<i>Gutach Riv.</i> , Bavaria. "Stone." [1905?]	Spandrel walls. Railroad.
9*	209.9	(<i>Cr</i> =3.4).	<i>Bogenhausen</i> , over Isar R., Bavaria. "Stone." [1902.]	2-hinged arch, 21.4 ft. rise. Highway.
10	200.	(<i>Ris</i> =42, <i>Rad</i> =140, <i>Cr</i> =4.6, <i>Sp</i> =7).	<i>Grosvenor</i> , over Dee, Chester, Eng. "Circular." [Hartley, 1833.]	

* Described also in Table 6.

5.—SOME NOTABLE ARCHES THAT HAVE BEEN BUILT.—Continued.

No.	Span.	(Dimensions.)	Name and "Kind." [Engineer and Date.]	Remarks.
11	196.8	(Ris=52.8, Cr=5.6, Sp=13.8).	<i>Gowr Noir</i> , France. "Circular." [Draux, 1888.] Railroad.	
12*	187.5	(Ris=32.2).	<i>Lautrach</i> , over Iller, Bavaria. "Concrete." [1907.]	
13*	187.	(Ris=55.8, Cr=6.56, Sp=9.18).	<i>Schwaenderhols</i> , on N. & D. Ry "Stone." Railroad.	
14	181.	(Ris=90.5, Rad=90, Cr=4.5, Sp=6).	<i>Ballochmyle</i> , Ayre, Scotland. "Circular." [Miller.] Railroad.	
15	164.	(Ris=16.4, Cr=3.3, Sp=3.6).	<i>Munderkingen</i> , over Danube. "Circular." [Bois, 1893.] Hinged arch. Railroad.	
16*	164.	(Ris=15.75, Cr=1.77, Sp=2.98).	<i>Chattellerault</i> , France. "Reinforced concrete." [1902-] Four arched ribs. Hennebique system. Highway.	
17	159.	(Ris=28, Cr=4.5, Sp=6).	<i>Wheeling</i> , W. Va. "Circular." [Hogue and White, 1893.]	
18	152.	(Ris=37, Rad=162, Cr=4.9, Sp=10).	<i>London</i> , over Thames, Eng. "Ellip." [Rennie, 1831.] 5 spans.	
19	150.	(Ris=35, Rad=98, Cr=4.5).	<i>Gloucester</i> , over Severn, Eng. "Ellip." [Telford.]	
20	150.	(Ris=27, Cr=3.8, Sp=4.5).	<i>Elyria</i> , Ohio. "Sandstone; circ." [Kinney, 1886.] Highway.	
21	148.	(Ris=18, Rad=160, Cr=4.92).	<i>Turin</i> , Italy. "Circular." [Mosca.]	
22	144.	(Ris=19.3, Cr=4.2).	<i>Putney</i> , over Thames, Eng. [Bazal-zette, 1886.] 4 other spans.	
23*	143.87	(Ris=19.03, Cr=4.10, Sp=4.78).	<i>Orleans</i> , over the Loire, France. "Stone; catenoid." [Renardier, 1906.] Highway. 70 spans.	
24	141.	(Ris=28, Rad=103, Cr=4.92).	<i>Alma</i> , Paris. "Small, cement rubble; ellip." [Darcel.] Railroad.	
25	140.	(Ris=35, Rad=88, Cr=1.5+1, Sp=2.5+).	<i>Pont-y-Prydd</i> , over Taff, So. Wales. "Rough rubble in lime mortar; circular." [Built by a stone mason in 1750, to replace a former bridge of the same general design which fell on striking centers; present bridge, however, has spandrel openings which former bridge did not.]	
26*	140.	(Ris=30, Cr=5+2).	<i>Ill. Cent. R. R.</i> , over Big Muddy. "Concrete; ellip." [1903.]	
27	131.2	(Ris=18.2, Cr=3, Sp=3).	<i>Coulouvreniere</i> , France. "Circ." [Bois, 1896.]	
28	128.2	(Ris=32, Cr=5.1).	<i>Neuilly</i> , Seine, France. "Ellip." [Perronet, 1773.] Arch settled 2 ft. on removing center, and radius at crown increased from 160 to about 250 ft.	
29	128.	(Ris=24.2, Rad=169, Cr=5.25, Sp=7.2).	<i>Maidenhead</i> , Eng. "Brick in cement; Ellip." [Brunel, 1837.] Railroad.	
30*	125.	(Ris=39, Rad=67.75, Cr=5, Sp=7.67).	<i>Piney Branch</i> , Wash., D. C. "Concrete; parabolic." [Douglas and Darwin, 1906.] Highway.	
31	124.	(Ris=6.92, Rad=281, Cr=2.67, Sp=3.60).	<i>Experimental Arch at Souppes</i> , France—See No. 32. "Cut granite in Portland cement; circular." [Vaudrey, 1866.] Width, 12 ft. Ratio span to rise, 17.83. Centers struck in 4 mos.; deflection 1½ ins. Tested without injury by distributed load of about 500 lbs. per sq. ft.; also by weight of about 5 tons falling 18 ins. on key.	

* Described also in Table 6.

5.—SOME NOTABLE ARCHES THAT HAVE BEEN BUILT.—Continued.

No.	Span.	(Dimensions.)	Name and "Kind." [Engineer and Date.]	Remarks.
32	124.	(Ris=6.92, Rad=231, Cr=2.67, Sp=3.60).	<i>Bourbonnais</i> , France. "Cut granite; circ." [Vaudrey.]	Very bold; built after experiment at Souppes, preceding. Railroad.
33	120.	(Ris=31, Rad=112, Cr=4.5, Sp=8.)	<i>Waterloo</i> , over Thames, London. "Granite; ellip." [Rennie, 1816.]	8 other spans.

Concrete Culverts.

Fig. 26 is a section of a small railroad culvert, 8 ft. wide and 3 ft. high, which has been used considerably on the Penn. R. R. as a standard. The amount of concrete required is about 0.41 cu. yd. per lin. ft. of culvert.

Fig. 26.

STEEL AND COMBINATION ARCHES.

A few hints will be given to illustrate the method employed in the calculation of some of the forms of steel arches most commonly used in practice. Steel arches differ from stone arches in that they are designed to resist bending, as well as compression and shear. In other words, the line of resultant pressure is not confined within any given limits but may pass anywhere outside the middle third or even outside the rib of the arch altogether. Hence the form of arch selected, and depth of rib or truss, are matters of economy, adaptability and appearance, rather than of mere gravitational stability of the respective parts.

In the following discussion it is assumed that the forms of the structures have been determined, the problems being to find the stresses in the various members or parts under certain given loadings. The first thing to do in each case is to find (one or more of) the reactions at the points of support; and when these are known the remaining solution reduces to the simple case of "finding the inner forces or stresses when the outer forces are given," that is, to the case of any simple structure.

The methods used in finding the reactions may be wholly analytical or partly graphical. The latter is chosen here for simplicity. The first step is to draw the arch and its "position line," sometimes called the "locus line."

Arch with No Hinges.—This arch (Fig. 27) is seldom used in practice, the 2-hinged and 3-hinged arches being mainly employed. The position line is laid off by means of an equation containing x and y . From any point p the direction of the reactions for any load P may be obtained by either one of several methods: (1) by drawing lines from any point a as p tangent to the reaction curves; (2) by calculating the vertical ordinates y_1 and y_2 from the points a and b , to points on the line of direction of the reactions; (3) similarly, by calculating x_1 and y_1 ; (4) by calculating the right angle offsets from a and b ; (5) by calculating the horizontal thrust H ; etc. The force polygon, above, gives the value and direction of R_1 and R_2 . The equation for giving these values vary with the form of arch, direction of loading, etc., and will not be given here. The temperature stresses have also to be considered.*

Fig. 27.

Two-Hinged Parabolic Arched Rib.—Let the curve ab (Fig. 28) be the neutral axis of the rib with end hinges at a and b . The "position line" may be determined from the

formula $y = \frac{6.4 c^2 h}{5c^2 - x^2}$, for any value of x on either

side of the vertical axis; c being the half span, and h the rise. The reactions R_1 and R_2 are obtained for any force P at point p by drawing the triangle of forces as above. These reactions must pass through or act at the hinges a and b . H_1 and V_1 are the horizontal and vertical components of R_1 ; H_2 and V_2 of R_2 . The bending moment at any point m is equal to R_2 multiplied by the offset d . The axial thrust due to R_2 must also be considered in designing the flanges of the girder; and the shear, in designing the web. A table may be made showing the bending, compressive and shearing stresses at various points m along the girder due to loads P at successive positions, and summarized, being careful to use the proper + and - signs.

The above method is exact only for shallow, solid ribs of constant cross-section; but it is used also for plate girders and open ribs even when the flange plates do not extend to the hinges.

Fig. 28.

panel load P at e . Draw the Position Line as shown, and from the directly above e , lay off by scale the load P , vertically. Then by of forces find R_1 acting in the direction ap . To find the stress S a cutting plane through the panel and find the origin O at the

intersection of the other two active members ac and ad . Taking moments about O , of the forces acting at the left of the cutting plane, we have, using the lever arms m and n , $mS = nR_1$, or $S = \frac{n}{m} R_1$ (tension). Similarly, the stress in any member may be obtained for any loading.

COST OF REINFORCED CONCRETE ARCH BRIDGES.

Highway Bridges.—Cost per square foot of floor for 50-ft. spans, \$2.00 to \$2.50; 75-ft. spans, \$2.50 to \$3.50; 100-ft. spans, \$3.50 to \$4.50; 125-ft. spans, \$4.50 to \$6.00; 150-ft. spans, \$6.00 to \$10.00.

Electric-Railway Bridges.—Cost per square foot of floor for 50-ft. spans, \$3.50 to \$4.00; 75-ft. spans, \$4.00 to \$4.50; 100-ft. spans, \$4.50 to \$5.00; 125-ft. spans, \$5.00 to \$6.50; 150-ft. spans, \$7.00 to \$10.00.

Steam-Railway Bridges.—Cost per lineal foot, double track, for 50-ft. spans, \$200 to \$250; 75-ft. spans, \$250 to \$275; 100-ft. spans, \$275 to \$300; 125-ft. spans, \$300 to \$325; 150-ft. spans, \$325 to \$350.

45.—TRESTLES.

A Trestle is a bridge composed of a series of relatively short beam- or girder spans resting on "bents," which take the place of ordinary piers.

Pile Trestles.—Where the bents are composed of piles it is called a pile trestle or pile bridge. Each bent may consist of any number of piles driven in line transversely with the axis of the bridge, the number required depending upon the kind of bridge, the width, loading, height of trestle, kind of soil, lateral stiffness required, whether on tangent or curve, etc. Generally, the piles are driven vertically but where great stiffness is required the end piles of each bent are driven commonly on a batter. In fact, this latter practice is usual with some railroads even for low trestles on tangents. The cost of driving such batter piles is not excessive, as the gins of the driver may be arranged easily so as to swing laterally on a pivot like a pendulum. For a foot bridge, two or more piles are used to the bent; for a highway bridge, three or more; and for a railroad bridge, four or more.

The maximum load on a pile should be limited to about 40,000 lbs., and a load of 25,000 to 30,000 lbs. is preferable, usually. If driven in soft material a less load should be used. Again, the loading on pile may be limited to the allowable compression "across grain" of the wooden cap resting upon it. Piles should be peeled before driving unless they are driven in salt water.

Wooden caps are usually 12 x 14 ins. for railroad bridges; 12 x 12, 10 x 12, 10 x 10, etc., for highway bridges—with greater dimension vertical. The piles when driven are sawed off on a plane, either level or inclined (to give proper elevation to outer rail if on a curve), and the caps are drift-bolted to them. The usual size of drift bolt is $\frac{1}{2}$ to $\frac{3}{4}$ in. in diam., and 18 to 22 ins. long. Holes are first bored with an auger about $\frac{1}{8}$ in. smaller in dia. than the bolt.

Diagonal bracing for each bent consists usually of two planks, one on either side of bent and crossing at the middle line, with upper ends bolted to caps near their outer ends, and with lower ends bolted to the outer piles—using $\frac{1}{2}$ -in. screw bolts and cast washers. At intersection with the inner piles the braces are fastened to same with two wrought spikes with length at least twice the thickness of the planks. Similarly, horizontal "sash" braces may be fastened to the piles on both sides of the bent at foot of diagonals. For railroad trestles, 4 x 10 in. bracing is common; and for highway bridges, 3 x 10, 3 x 8, 2 x 10, 2 x 8, etc. High trestles are double braced.

Standard Plans for Pile Trestles.

Each railroad has its own standards, differing in certain essential details from those of other roads, such, for instance, as spacing of stringers and jack stringers, arrangement and size of guard rails, and the design of the floor in general.

Fig. 1 is an elevation of bent of single track trestle of the Oregon Short Line R. R., showing ballast floor.

Timber Trestles.—The term "frame trestles" is applied to those trestles constructed of framed timbers, usually sawed to "dimension," but sometimes consisting of straight, round poles or piling timbers denuded of the bark. The latter construction has been used considerably in the Pacific-Northwest. Where such poles are used the posts are commonly in one length, even for very high trestles.

Ordinarily, however, the bents of high trestles are constructed in sections, vertically: A single-deck trestle is one in which the bents are in one section; double-deck, in two sections; 3-deck, in three sections; etc. Fig. 2 is an illustration of a 3-deck trestle showing the right half resting on piling, and the left half resting on mud-sills, the latter being used in cases where piles cannot be driven or where the cost of driving is prohibitive. The mud-sills should be of cedar, about 8 x 12 ins. by 4 ft. long, and laid side by side on a well tamped foundation thoroughly drained and free from

wash. Instead of *driving* piles, "false" piles, *set* by hand, are sometimes employed. Concrete or rubble masonry piers are desirable where a suitable sub-foundation is presented cheaply.

Fig. 1. (See page 787.)

Fig. 2 illustrates a more or less typical railroad trestle which will be described briefly: The main posts, 12×12 ins., have a continuous batter of $3:12$ and $1:12$. They are "dapped" into the caps and sills about $\frac{1}{4}$ in., drift-bolted at tops, and doweled (with 1-in. round iron) and toe-nailed (with wrought spikes) at feet. (Mortise and tenon joints are no longer used.) The "batter" posts, used below the top deck, are likewise framed, drift-bolted, doweled and toe-nailed. They give lateral stiffness as well as vertical support. The main caps and sills are 12×14 ins., while the intermediate caps and sills are 12×12 ins., extending 12 ins. or more beyond the outer edge of posts. Each section of the bent is sway-braced with 4×10 in. plank, screw-bolted at ends, and spiked at intersections. The bracing between the bents consists of 12×12 in. longitudinal girts G , framed into the intermediate caps and sills, with lap joints, and thoroughly drift-bolted to them; and the longitudinal diagonal braces L consist of 4×10 in. plank, screw-bolted at ends. The floor of the bridge rests on two lines of main stringers and the two lines of jack stringers, the latter being used as safety stringers in case of derailment. Main stringers are ordered in 2-span lengths, that is, for bents 15 ft. centers they are ordered 30 ft. long, laid two, three or four to each line with alternate and butt joints, dapped over the caps and drift-bolted thereto. They are separated about 1 inch laterally by cast spool separators through which the screw bolts are inserted (using cast washers), four to each joint over the caps. Between the lines of stringers a 4-in. plank of proper length is spiked to top of caps to preserve the required stringer spacing. The jack stringers are ordered one foot longer than the main stringers (or say 32 ft. long) so that the joints can be "halved" and drift-bolted to caps with one

bolt. The practical sizes of main stringers are 8 x 14, 9 x 16, 10 x 18, using two or three (or more) stringers under each rail. The width of jack stringer should be not less than 6 ins., and it should not be less than about one-third the width of one line of main stringers. High trestles are provided usually with outer guard rails or "bull" rails, which have, in certain cases, prevented trains from plunging over the side of the bridge. These bull rails are preferably about 12 ins. high, and 10 x 12 in. timbers are commonly used. They may be ordered in any convenient lengths, are halved like the jack stringers, and secured firmly by screw bolts passing vertically through bull rail, tie and jack stringer. In addition to the bull rails or "outer" guard rails, there should be "inner" guard rails. The inner guard rails are usually common rails placed inside the main rails, but wooden guard rails, say 5 x 8 ins. (5 ins. vertical), dapped over the ties to preserve proper spacing of the

Fig. 2.

latter, are frequently used. They are secured to the ties by wood or lag screws (8 or 9 in.) with heads flush with top of guard and bearing on flat washers. Sections of bents are from 20 to 24 ft. in height and uniform from top of bridge downward so that the various decks are on planes parallel with the track. Longitudinal diagonal bracing may generally be omitted between alternate pairs of bents.

Many modifications may be made of Fig. 2. For instance, the inner main posts may be vertical; all the main posts may be continuous (each composed of one stick, or of two sticks bolted together with alternate joints) and the transverse diagonal bracing divided by horizontal sash braces spaced vertically about the depth of one deck, with longitudinal girts bolted at intersections of sash braces and posts; instead of having separate intermediate caps and sills, one piece may serve to act as the cap of the section below as well as the sill of the section above; etc.

Grass-hopper bents, Fig. 3, are often used with economy on side-hill work; either to save cost of excavation or to avoid encroachment on ad-

Fig. 3.

joining property. The writer has used as many as three broken sills to the bent with perfect safety and even without concrete backing to resist thrust. At *a*, the upper broken sill is dapped into the post one inch and sash braces are spiked and bolted on as shown in Fig. 3. Careful attention should be paid to drainage.

The bents of wooden trestles are spaced usually from 12 to 16 ft. centers, the ordinary spacing being, perhaps, 15 ft., calling for 30-ft. stringers which are shipped conveniently on the average flat car. Unlike steel trestles the spacing is constant or nearly so throughout the bridge, regardless of the variation in height of bents. Where long spans are introduced in a wooden trestle, as for spanning a creek, the supporting bents are usually doubled or tripled.

On curves, the caps are inclined in order to give proper elevation to the outer rail. This method is preferable to using level caps, with shins under the stringers or on the ties, etc., as is sometimes done. The writer generally supplies the foreman of the framing crews with tables giving the increased lengths of posts on outside of curve and the decreased lengths on inside of curve for each bent, to provide for the proper elevation of the outer rail and a like depression of the inner rail, each being one-half of the required "elevation."

Pile and Timber Trestles.—A pile and timber trestle is one in which the piling of the foundation is cut off high enough above the ground to

Fig. 4.

constitute the lower deck, and on which the timber trestle proper is erected. Sometimes, however, the term is applied to a frame or timber trestle with simply a pile foundation.

Fig. 4 is a section of a pile and timber trestle of the A. T. & S. F. R. R.

LE BENDING MOMENTS IN FT.-LBS. ON WOODEN STRINGERS.

By Formula, $M = \frac{1}{8} f b d^2 \div 12$

f = allowable outer fiber stress in lbs. per sq. in.;

b = breadth of stringer, in ins.;

d = depth of stringer, in ins.

[Values of M in Ft.-Lbs.]

000	66 667	120 000	133 333	180 000	200 000	240 000

are directly proportional to width of stringer, and to (depth)².

—Find the size of wooden stringers required for 15-ft. spans, the engine load to give a maximum bending moment of 298500 ft.-lbs. per track, and assuming the floor to weigh 450 lbs. per lin. ft. per the stringers 420 lbs. per lin. ft. of track).

—Total bending moment = $298500 + \frac{870 \times (15)^2}{8} = 322969$ ft.-lbs.

31485 ft.-lbs. per rail. From the above table this calls for 4— stringers under each rail, if the outer fiber stress is assumed at 900.

stles.—The proper and economical design of a steel trestle for any site calls for a thorough examination of the site. In addition to and contour map, borings may be required to determine the sub-foundation. The spans are longer than for wooden stringers, and are made to increase with the height of the structure so that the rule "The cost of piers should equal cost of spans" will apply

active feature of steel trestles is that there are few posts to the trestle, two posts are sufficient for single track railroad trestles.

With trestles the bents are usually arranged in pairs, each pair of bents is arranged horizontally and diagonally, both longitudinally and transversely, sometimes laterally, really forming a steel pier.

In consideration in design it may be noted that, as far as the floor of the spans alone is concerned, that floor is the most economical part of the structure; that is, for any given number of supports the spans should be spaced equidistant throughout to give the least cost of the structure as a whole we have second that the cost of the structure with its foundation, should equal the cost of the portion which it supports (Fig. 5). Hence the profile, character of the spans, etc., have considerable influence in varying the lengths of the spans. In testing the economy of the spans let us assume any portion as DG to be fixed and equal to l_0 . Now any small increase in l_0 will require an increase in

approximately; see Sec. 37, Bridges, page 683.

the amount of material in both the span and bracing between bents B_1 and B_2 , and a decrease in material in spans S_4 and S_6 . Conversely, any decrease in l_5 will produce the opposite effect. Hence, l_5 should be such that for any small change in its length the increase in material on the one

Fig. 5.

hand will just equal the decrease on the other. But note that in the similar adjustment of adjacent portions the above spans may require re-adjustment; and likewise, all other sections. We have also to take into consideration the best *relative* lengths of l_2 , l_4 , l_6 , etc. Tables or diagrams showing the weights of spans, bents, and bracing for various lengths and heights for the particular loading will greatly facilitate the above adjustments.

The floor system is arranged similar to that of an ordinary steel bridge, that is, with floor beams and stringers, the former being supported directly by the bents. For short spans, I-beams may be used; for longer spans, plate girders. For very long spans both floor beams and stringers may be trussed, using deck girders for this purpose.

The posts of the bents (Fig. 6.) are battered about 1 : 6 — considerably less than for wooden trestles. This narrowing of the space between posts tends to call for less metal in the transverse bracing; for more metal in the posts, from wind stresses; but for slightly less metal in the posts from direct loads. The best designs have stiff diagonal bracing instead of rods, and large members with few connections are preferable. The feet of columns should be anchored. The wind stresses may be calculated by treating the bent as a cantilever arm, assuming all the joints to be hinged; but if the framework is stiffened by heavy gusset plates, and riveted connections are used, it becomes statically indeterminate.

Fig. 6.

Elevated Railroad Trestles.—For a full discussion of this subject the reader is referred to Paper No. 806, Trans. Am. Soc. C. E., June, 1897, by Mr. J. A. L. Waddell.

Reinforced Concrete Trestles.—The outline shown in Fig. 6, above, for steel trestles, is a good design for a high trestle bent of reinforced concrete. It can also be modified as follows: (a) By omitting the horizontal braces, using the diagonal bracing only; (b) by omitting the diagonal braces, using the horizontal bracing only; (c) by omitting all bracing. In case (b), however, the mushroom connections of horizontal braces to posts must be of the large gusset type, in order to introduce bending resistance at ends of braces; and similarly at the floor-beam connections. Case (c) should be used for short bents only.

The posts and bracing should be calculated for live-, dead- and wind loads; for centrifugal force due to moving load if trestle is on a curve (see page 702); and for longitudinal thrust or momentum due to stopping of trains (page 702).

For proportioning the members, see pages 585 and 609; also page 446 for beam and column formulas.

References to numerous designs and details may be found on the following page.

COST OF RAILROAD TRETTLES.

Timber Trestles.—(a) *Single Track*. Cost in dollars per lin. ft. (approx.) = $-8 + 0.2H + 0.002H^2$. *Double Track*. Cost in dollars per lin. ft. (approx.) = $16 + 0.4H + 0.003H^2$. In which H = height of trestle bent, in feet.

Steel Trestles.—About three to five times the cost of timber trestles.

Reinforced Concrete Trestles.—Low trestles cost about the same as small arch spans. See page 784.

Table for Estimating Quantities in Timber Trestles (By Emile Low. Eng. News, April 22, 1909).

Reinforced-Concrete Viaduct with Some Structural Steel Reinforcement (Eng. News, July 1, 1909).—Tower bents composed of two posts, 18 x 18 ins. square at the high bents and 15 x 15 ins. at the low, spaced 12 ft. c. to c. at the girders and extending on an outward batter of 1 : 6 to spread foundations on solid rock. Posts are concrete reinforced at the four corners by straight round rods, encircled every 12 ins. with $\frac{1}{4}$ -in. wire. Longitudinal and transverse braces are 9-in. and 12-in. I-beams encased in concrete. Illustrated.

Reinforced-Concrete Trestle, Pasadena, Cal. (Eng. News, Nov. 18, 1909).—Consists of six girder spans resting on five tower bents; whole length divided into panels of 17 ft. 3 ins., each bent being of that length, and each span divided into three of such spaces by the floor beams, making a span length for each girder of 51 ft. 9 ins. Towers consist of four columns; each; columns 18 x 18 ins. and reinforced with eight $\frac{1}{4}$ -in. round steel bars extending into the pier footings to within one foot of their base. Nearly all the columns are over 50 ft. long and have longitudinal and transverse struts framing into their third points to stiffen them. Struts vary in size from 10 x 18 ins. to 12 x 24 ins. and are reinforced with four $\frac{1}{4}$ -in. or four 1-in. twisted steel bars laced as a column. Illustrations include details of expansion joint.

46.—ROOFS.

Wind Pressure.—The problem of wind pressure which indirectly presents itself to the engineer consists in discovering the existing relation between the *velocity* of the wind and its *pressure* against any surface—right, oblique, plane, curved, etc. Then, knowing the maximum velocity of the wind in the particular locality in which a structure is to be erected, the probable pressure on its surface is deduced within a reasonable degree of accuracy by this ratio. The subject never has been treated satisfactorily on the grounds of pure theory, while the few practical experiments recorded seem to give results not entirely in accord with each other nor with any theory yet advanced.

Velocities Attained.—The velocity of a volume of air moving along the surface of the earth increases with its distance above the average surface, hence high structures, or those in exposed positions, should be designed to resist the greater wind pressures in any locality. Prof. Henry claims that on Mt. Washington, N. H., 150 miles per hour has been recorded. This probably exceeds by over 50% the maximum velocity ever attained at the average surface of the ground in that State. The tornado which tore up a portion of the St. Louis Bridge floor is credited with but 120 miles per hour. A hurricane such as occasionally visits the Atlantic coast may attain a velocity of 60 miles per hour upward, depending upon exposure. From 90 to 100 miles per hour is probably the maximum velocity ever attained in New York City in the most exposed positions. The Pacific coast is never visited by the violent hurricanes incident to other sections of the country.

Direct Wind Pressure.—When the atmosphere is at rest it exerts a pressure at sea level of about 14.7 lbs. per square inch; while a cubic foot of dry air under one atmospheric pressure (760 millimeters of mercury) weighs about 0.081 lb. per cubic foot. Wind is air in motion caused by a tendency to restore equilibrium in atmospheric pressure, at about the same level, by air rushing in to replace a heated and rising atmosphere in another locality. Hence, the directing force is a *tension* or tendency to partial vacuum "ahead" of the wind, as well as a compression from behind. It is well to bear this in mind, as explaining in part at least the uplifting or overturning power exerted on roofs, due to *suction*. This suctional power is not well known, and its effect should be considered more in future experiments and investigations. Some attempts have been made to deduce a rule for pressure, based on the weight of the volume of air moving against the exposed surface, taking into account temperature, humidity and barometric pressure, but the results have been more or less unsatisfactory.

Smeaton, 150 years ago, made some crude experiments on wind pressure in connection with the power of windmills, and constructed a table from the formula

$$P = .005 V^2 \dots\dots\dots (1)$$

in which P = horizontal normal pressure in lbs. per sq. ft.,

and V = velocity of wind in miles per hour.

This formula seems to agree fairly well with many experiments on small surfaces. Another formula, of the same form as Smeaton's, giving results 20% less, is used considerably:*

$$P = .004 V^2 \dots\dots\dots (2)$$

In both of the above the pressure is assumed to be proportional to the *square* of the velocity. Lieut. Crosby's experiments near Baltimore, Md. (*Engineering*, June 13, 1890) to determine the resistance of the air to fast moving trains seem to indicate that the pressure P is directly proportional to the velocity V , and not to V^2 . But this conclusion is generally discredited.

The conclusion from Baker's experiments in connection with the construction of the Forth Bridge is that the pressures given by Smeaton's formula (1) are too great for high velocities. In the light, or perhaps better

* This formula is now used by the U. S. Signal Service.

"darkness," of modern experimental data, the pressure P may be assumed to lie somewhere between the values given by formulas (1) and (2)—near the former for low velocities, and near the latter for high velocities. These values are deduced in the following table; and two columns are added giving results from the experiments of Eiffel and Stanton.

1.—DIRECT NORMAL WIND PRESSURES.

Before considering the resolution of a direct wind pressure into its normal, vertical and horizontal components, as practically applied to roofs and other structures, it will be well to emphasize the above hints regarding pressure and tension (suction) on any exposed body. If the surface of a thin flat sheet is exposed to the direct force of the wind, there will be tension or suction on the leeward face, due to partial vacuum, thus producing apparently additional pressure on the windward face and as these forces act in the same direction, the resultant "wind pressure" is thereby increased. The tension may be reduced by placing a long tapering projection on the leeward face of the plate, flush with the edge, to prevent the formation of air eddies. Further, if the windward face is convex, the pressure also will decrease, while if it is concave the pressure will increase. The thickness of the plate within certain limits is also a factor, as well as the density and humidity of the atmosphere.

Fig. 1.

Normal and Component Wind Pressures.—Let P , Fig. 1, be the direct horizontal pressure per square foot on any vertical surface, and P_n the normal pressure on the same unit of inclined surface, sloping at angle A with the horizontal. Then—

By Abstract theory, $P_n = P \sin^2 A$ (3)

By Hutton's experiments, $P_n = P (\sin A)^{1.94 \text{ or } A-1}$ (4)

By Duchemin's formula, $P_n = P \frac{2 \sin A}{1 + \sin^2 A}$ (5)

The following table gives values of P_n deduced from these three formulas, assuming $P = 50, 40$ and 30 lbs. Use Hutton or Duchemin.

*From experiments by M. Eiffel and Dr. Stanton; on velocities of 40 to 90 miles per hour. See, also, remarks under Railroad Bridges, Section 38, page 697.

*The normal pressures given in the table are in lbs. per square foot of inclined surface of exposed roof—from horizontal winds producing pressures of 50, 40 and 30 lbs. per square foot on vertical surfaces.

Example.—Assuming direct wind pressure to be 50 lbs. per square foot of vertical surface, and using Hutton's formula, find from the above table the normal pressure in lbs. per square foot on a roof with a pitch of one in two.

Answer—45 lbs. per square foot.

In designing roofs and buildings it is convenient to use the normal pressure against the roof surface, and to know also its vertical and horizontal components. The subjoined table gives these values for the 5 standard pitches* of roofs, and based on Hutton's and Duchemin's formulas at 50, 40 and 30 lbs. direct wind pressure. See table 2, preceding.

3.—WIND PRESSURES IN LBS. PER SQUARE FOOT ON ROOFS.

	1-4	26°-34'	37.3	16.7	33.4	29.8	13.3	26.7	22.4	10.0	20.0
	1-3	33°-41'	42.4	23.5	35.3	33.9	18.8	28.2	25.5	14.1	21.2
	1-2	45°-00'	47.2	33.4	33.4	37.7	26.7	26.7	28.3	20.0	20.0

Probably the low direct pressure value of 30 lbs. per square foot, reduced by Hutton's† (or Duchemin's) formula will be sufficient for general cases; the next higher value, 40 lbs., for particularly exposed positions; and the highest value, 50 lbs., for special cases as in the tornado belts.

In open sheds the maximum direct pressure may be assumed as acting normal to the inside leeward surface, and the "lifting" force may be obtained by multiplying the total direct pressure by $\cos A$, the angle of inclination of roof with the horizontal.

On a cylinder the theoretical pressure is $\frac{3}{4}$ that on a corresponding plane diametrical section or rectangular plate; but Borda, by experiment, found it to be only 0.57. Likewise, he found the pressure on a sphere to be but 0.41 of that on a corresponding circular plate of the same diameter, while theory gives $\frac{3}{4}$. In general, the pressure on a concavity, measured by the diametrical plane surface, is greater than unity; while on a convexity it is less than unity. The intensity of pressure may be increased by the deflection of the wind from an adjacent structure.

Fig. 2.—Roof "Pitches."

Snow Loads.—The snow loads which may come on a roof will vary with the latitude of the place; its altitude above sea level; the general humidity of the atmosphere; the winter temperature; the location with respect to mountain ranges; the pitch of the roof (Fig. 2); the character of roofing. The writer is familiar with the character of the snow fall in nearly every State in the Union and in Canada. For the Pacific slope west of the Coast and Cascade mountain ranges, there is no need to provide for any snow-load, but up in these ranges and in Eastern Washington, Eastern Oregon, Northern California, and in all sections eastward to the Atlantic coast, provision must be made. The heaviest snow-falls in the United

* The pitch of a roof is one-half the natural tangent of inclination with the horizontal.

† The writer believes Hutton's formula, founded on practical experimental data, to be quite well established and fairly reliable. Duchemin's formula gives values about 25% higher for the ordinary 1-4 pitch.

States are in the Central Northwest, New England and the Rocky Mountain regions. The following diagram, giving the snow load per horizontal square foot of roofs for different localities and for standard roof pitches, will be found practically reliable. The latitude of the place is considered as increased one degree for each thousand feet in altitude above sea level.

Fig. 3.

Example.—To find the snow load in pounds per horizontal square foot at Denver for a pitch of 1 in 5? The latitude of Denver, 40, plus 1000 of its altitude in feet above sea level, 5, gives 45. Using line (b) of above diagram this is equivalent to a snow load of 28.2 lbs. per horizontal square foot for a pitch of 1-5.

Investigations by S. de Perrot, in Switzerland, according to the "Engineer" (London), show that where a heavy fall of snow is followed by thawing and freezing and then more snow, in repeated cycles, the laminar mass of snow and ice will have a weight of 36 to 38 lbs. per cu. ft.; and the thickness of the mass on the roof, from 24 to 32 ins., will produce a load of 70 to 100 lbs. per sq. ft., about 2 to 4 times the weight ordinarily assumed in calculations.

Roof Coverings.—Materials for roof covering are selected for protection against rain, snow and other natural agencies. They should be light, durable, economical and more or less artistic; and their selection will be dependent on the character of the building, its location with respect to climate, the amount of acids and injurious gases in the atmosphere, and the pitch of the roof. Among the most commonly used materials for "pitch" roofs are shingles, slate and tile for residences; slate, gravel and tile for railway structures; corrugated steel for warehouses. For temporary structures, as exposition buildings, the patented roofings are generally used, and then relaid elsewhere. For "flat" roofs, tin, tar and gravel, asphalt, and other compositions are preferred.

* West of the Coast and Cascade Mt. ranges. † In general.

Shingle Roofing.—Shingles are made of white cedar, red cedar, spruce, pine, fir and cypress.* In the United States the life, in years, of cedar shingles will correspond to about the latitude of the place in degrees; pine will last about one-third to one-half as long as cedar, depending upon the climate. The following table is based on shingles 4" wide, and with an average thickness of $\frac{1}{8}$ ". The weight of cedar is assumed at 36 lbs. and pine at 40 lbs. per cubic foot. The length of shingle is a little over 3 times the "weather."

4.—WEIGHT OF SHINGLES 0.2 INCH THICK, LAID ON ROOFS.

(Weight is proportional to thickness of shingles.)

Length. Ins.	Assumed Width. Ins.	Weather or Gage. Ins.	Shingles per Square of 100 Sq. Ft. Number.	Weight per Square of 100 Sq. Ft.		Nails per Square. Number.	Weight of Nails per Square. Lbs.
				Cedar. Lbs.	Pine. Lbs.		
14	4	4	900	210	233	1800	4.50
15	4	4½	800	200	222	1600	4.00
16	4	5	720	192	213	1440	3.60
18	4	5½	655	197	218	1310	3.28
20	4	6	600	200	222	1200	3.00
22	4	6½	554	203	226	1108	2.77
24	4	7	515	206	229	1030	2.58

Shingles are nailed directly on shingle laths or on solid 1" sheathing covered with tarred paper, using two 1½" nails to each shingle. The laths are from two inches wide upward, spaced a few inches apart, and nailed horizontally to the jack-rafters.

Slate Roofing.—Slates are laid shingle fashion. The length of slate is usually 2 times the "weather" + 3 inches. The following table is based on the above. The number of slates per square of 100 sq. ft. = $14,400 \div (\text{width} \times \text{weather})$.

5.—NUMBER OF SLATES PER SQUARE, LAID ON ROOF.

24	414	621	828	1242	1657	2071	2485	3313
26	410	615	820	1230	1639	2048	2459	3278

Note.— $\frac{3}{4}$ " slates are the most common.

Slate may be nailed on wooden sheathing, laths, porous terra cotta, reinforced concrete sheathing, etc., with or without felt between. The nails may be of malleable iron, copper, zinc, or composition metal. Iron or steel nails should be tinned or galvanized. The slates are often fastened directly to the sub-purlins by copper wire. Slater's cement makes a good tight bond and is recommended for flat pitch, which should not be less than 1-4 for slate roof.

Tile Roofing.—Tiles are made of terra cotta (baked clay), glass, and metal.

Clay tiles come in various shapes and under different names, as plain or flat, groove-and-fillet, pan, Spanish, etc. The plain clay tiles, say $6\frac{1}{2}$ "x $10\frac{1}{2}$ "x $\frac{5}{8}$ " thick, will weigh from 15 to 18 lbs. per sq. ft. of roof when laid $5\frac{1}{2}$ " to weather. The weight of porous terra cotta roofing in lbs. per square foot = 4 (thickness in inches + 1).

The M. W. Powell Co.'s* Specifications for a Tile Roof are: First cover the roof foundation with 6 thicknesses of No. 1 wool roofing felt, weighing not less than 15 lbs. (single thickness) per 100 sq. ft.; the felt to be laid smoothly and evenly, and well cemented together, not less than 9 ins. between each layer, with roofing cement. All joinings along the walls and around the openings to be made carefully. The roof then to be covered with actinolite cement, and vitrified tile to be laid on this surface, the joints of the tile to be made with marmolite cement. The tile to be $6\frac{1}{2}$ "x $9\frac{1}{2}$ "x $\frac{1}{2}$ " thick. All walls and openings should be flashed with copper. The surface of the roof foundation should be perfectly smooth before the felt is laid.

Glass tiles are used principally for skylights.

Metallic tiles, of copper, zinc, iron, tin, etc., are made up in artistic forms and laid as shingles.

Tin Roofing.—Tin plate proper consists of thin sheets of iron or steel coated with tin by dipping and rolling. When the molten tin is adulterated with lead the product is *terne* plate, which is much cheaper. For the base, "charcoal" plates are better than "coke."

Roofing tin comes commonly in sheets of two sizes,† 14 "x 20 " and 20 "x 28 ". As manufactured by the American Sheet and Tin Plate Co. of Pittsburgh, there are 112 14 "x 20 " sheets, or 56 20 "x 28 " sheets, in a box. The sheets are graded as "Primes" and "Wasters." The Primes or perfect sheets are branded according to thickness or weight of iron body, as IC ($\frac{1}{4}$ lb. per sq. ft.) and IX ($\frac{1}{2}$ lb. per sq. ft.). The IC 20 "x 28 " plates manufactured by Merchant and Evans, of Philadelphia, weigh about 215 lbs. net per box of 112 sheets, and the IX 20 "x 28 " plates weigh about 270 lbs. net. The IC and IX plates are supposed to have the same thickness of coating.

* Manufacturers of patent roofing materials, cements, etc., 204 Dearborn St., Chicago, Ill.

† Sheets may be obtained in sizes 10 "x 14 " and multiples thereof.

The tin sheets are laid on the roof in two ways, viz., with *flat seam* (Fig. 4), or with *standing seam* (Fig. 5). The flat seam is preferred for roofs of small pitch, using 14x20 plates; the standing seam for steep roofs, using 20x28 plates, generally. When laid with flat seam, a box of 112 sheets 20x28, containing 436 sq. ft. of plate, will cover about 384 sq. ft. of roof, about 12% being used in seams; and laid with standing seam it will cover about 370 sq. ft., with a loss of about 15%.

If 14x20 sheets are used, the percentage of loss is slightly greater. Inversely, to cover 1000 sq. ft. of roof will require 583 sheets of 14x20 if laid with flat seam, or 303 sheets of 20x28 if laid with standing seam.

For fastening flat-seam roofing, use 1" barbed and tinned roofing nails about 6" apart and well under edges of seams. In soldering use rosin (not acid) as a flux. In laying standing-seam roofing the sheets are locked and soldered together in long rolls from ridge to eaves. The standing seams are not soldered, but are locked together and held in place with tin cleats spaced 15 to 18 ins. apart, through which nails are driven.

Sheet Steel Roofing.—Sheet steel, "black" or galvanized, and of Nos. 26, 27 and 28 gauge, is used for roofing. It comes in sheets, or in rolls up to 50 ft. in length. The sheets are laid with horizontal flat seams, or by lapping, and with vertical standing seams, crimped, with tin fastenings.

Corrugated Steel Roofing.—Corrugated steel, "black" or galvanized, and of Nos. 16, 18, 20, 22, 24, 26 and 27 gage is usually laid directly on the purlins. To these sheets are fastened clips of various kinds by means of clinch rivets or bolts. The clips may hook under some edge of the purlin or pass completely around it, as in Fig. 6. They are usually spaced 12 inches apart. Corrugated sheets are rolled from plain sheets 30" wide and in lengths up to 10 feet. The standard corrugation is about 2½" wide and 1" deep, which narrows the 30" sheet down to 27½". Allowing for side lap, the net "weather" width is reduced to about 24". Lengthwise, the sheets should preferably rest on three purlins to give continuous-girder strength, although the strength is calculated for a simple span. The horizontal or "end" lap should be from 4" to 8", the latter for the flatter pitches and where the use of slater's cement is desirable. The *average* end lap is say 6", hence for sheets 4-ft. long the "weather" area is but 70% of the original flat sheet; 5-ft. long, 72%; 6-ft. long, 73.3%; 7-ft. long, 74.3%; 8-ft. long, 75%; 9-ft. long, 75.6%; 10-ft. long, 76%. In other words the weight of corrugated sheets per square foot of roof, laid, is respectively 43, 39, 36½, 35, 33½, 32½ and 31½ per cent. *greater* than that of the *plain* sheet metal. Galvanizing adds about one-third of a pound per square foot to flat metal, or, say, three-eighths of a pound per square foot to corrugated.

The strength of corrugated steel roofing may be obtained from the formula,

$$M = \frac{1}{9 \times 8} f b d t$$

In which M = bending moment or resisting moment, in *ft.-lbs.*;

f = allowable stress in lbs. per sq. in. in the metal;

d = depth of corrugations, in ins.;

b = breadth in ins. of loaded sheet *before corrugating*.

Tar-Gravel Roofing.—Gravel roofing is usually laid on wooden sheathing covered with roofing felt. The felt is laid in several thicknesses, with lap

Fig. 4.

Fig. 5.

Fig. 6.

(C).—The only correct method is to make the assumptions as near the true conditions as possible. Thus:

For short spans with both ends fixed, the wind load and reactions will be considered normal to one face of the roof as shown in truss and stress diagrams (h).

For long spans where one end of truss is fixed and the other end is a roller or sliding end, it should be calculated for that condition; namely, for wind pressure on the fixed side, and, again, for wind pressure on the roller side. See truss- and stress diagrams (j) and (o).

Generally, in all cases, it is good practice to design both halves of the truss symmetrically, using the maximum stresses obtainable by considering the wind pressure on either side of the roof, and either end of truss roller or fixed.

Note.—Nos. A, B, C and D correspond with similar Nos. in Tables 8 and 9.

Fig. 9.

9.—UNIT DEDUCTIONS FOR ONE-HALF TRUSS (LEAN-TO). Supplementary to Table 8.

(No deductions for web members.)

For unit stresses in *one-half* of each of the above trusses, considered as supported at points *a* and *b*, or *a* and *c*, make the following deductions:

Bottom chord members.—Deduct from the unit stress in each bottom chord member, as shown in Table 8, preceding, the unit stress in the center panel member of truss (as shown in black face type). The remainders are the unit stresses to be used.

Top chord members.—Deduction for each top chord member will be the bottom chord deduction multiplied by secant of angle of inclination of roof with the horizontal. For 1 to 3 pitch, secant = 1.202; 1 to 4 pitch, sec. = 1.118; 1 to 5 pitch, sec. = 1.077. The following data in connection with Table 8 will be found useful:

	A.	B.	C.	D.
Deduct for	Pitch 1-3: $1.202 \times 3.75 = 4.51$; $\times 3.00 = 3.61$; $\times 2.25 = 2.70$; $\times 1.50 = 1.80$.	Pitch 1-3: $1.118 \times 5.00 = 5.59$; $\times 4.00 = 4.47$; $\times 3.00 = 3.35$; $\times 2.00 = 2.24$.	Pitch 1-3: $1.077 \times 6.25 = 6.73$; $\times 5.00 = 5.39$; $\times 3.75 = 4.04$; $\times 2.50 = 2.60$.

Note.—Nos. E, F, G and H correspond with similar Nos. in Tables 10 and 11.

Figs. 10.

11.—UNIT DEDUCTIONS FOR ONE-HALF TRUSS (LEAN-TO).

Supplementary to Table 10.

(No deductions for web members.)

Bottom chord members.—Deduct from the unit stress in each bottom chord member as shown in Table 10, preceding, the unit stress in the center panel member of truss (as shown in black face type). The remainders are the unit stresses to be used.

Top chord members.—Deduction for each top chord member will be the bottom chord deduction multiplied by secant of angle of inclination of roof with the horizontal. Following are unit deductions for top chords:

Pitch	E	F	G	H
1-3	5.41	3.61	2.70	1.80
1-4	6.71	4.47	3.35	2.24
1-5	8.08	5.39	4.04	2.69

DESIGN OF COMBINATION ROOF TRUSSES.

Problem.—Trusses, 8 panels @ 9 ft. = 72 ft., spaced 14 ft. centers; pitch 1 to 4; height, $72 \div 4 = 18$ ft. Covering, slate laid on felt and 1-inch spruce sheathing. **Loads:**—Spruce sheathing, 3 lbs. per ft. B. M.; slate and felt, 9 lbs. per sq. ft.; snow, 20 lbs. per horizontal sq. ft.; wind, 30 lbs. per sq. ft. against vertical surface.

Solution.—For lack of space, hints only can be given. In this calculation it is assumed that the wind load and snow load do not act on the same face of roof at the same time; but may act separately on either side, or simultaneously on opposite sides: For maximum stresses in sheathing, jack-rafters and purlins, assume the wind load or snow load to act with the dead loads; for maximum stresses in the trusses, the wind load is assumed to act on one side of the roof and the snow load on the other at the same time, the wind load being considered as acting (1) on the fixed side, and (2) on the roller side; also (3) the snow load may be considered as acting on the whole roof without any wind load. The trusses are then designed symmetrically, using the maximum dimensions of twin members in either half of truss. The solution in detail is as follows:

Spacing of Jack-Rafters.

The horizontal sheathing is nailed to the vertically inclined jack-rafters, and these are laid directly on the horizontal purlins, which in turn rest on the top chord joints of the roof trusses.

Fig. 11.

length of the sheathing will determine, within certain limits, of the jack rafters, which spacing will be constant and some 14 ft., the spacing of the trusses. For the purpose of reference, and tangential pressures on roof surface for pitch of 1 to 4 (slope are given below:

	Pressure in Lbs. per Sq. Ft. of Roof.		
	Vert.	Normal.	Tangential.
Example 3, from Hutton's rule)	30.0	15.9	17.8
Normal = $20 \times \cos^2 26^\circ-34'$;			...
$20 \times \cos \alpha \sin \alpha$	17.9	16.0	8.0
Normal = $9 \times \cos \alpha$; tangen-			
$9 \times \sin \alpha$	9.0	8.0	4.0
Normal = $3 \times \cos \alpha$; tan-			
$3 \times \sin \alpha$	3.0	2.7	1.3

As can be noted in the above table that the normal wind pressure is considered the "direct" pressure, and 15.9 lbs. its vertical component. On the other hand, the vertical loads due to snow, slate and are the "direct" loads, and the normal and tangential forces are components. The snow load per square foot of roof = $20 \times \cos 26^\circ$ the sheathing, the normal pressure due to wind is greater than that of snow, but with the latter there is a tangential pressure of 8 lbs. to be added, which is lacking in wind pressure. Assuming the sheathing 4 ft. wide, the following two alternative conditions obtain as showing the load per lin. ft. acting on the sheathing:

Wind and dead loads on sheathing.

Fig. 13.—Snow and dead loads on sheathing.

allowable outer fiber stress per square inch (= 800 lbs. for spruce) and x = length of span in ft., we have:

$$\frac{28.5 \times x^2 \times 6}{12 \times 8 \times 1} \times 12 + \frac{5.3 \times x^2 \times 6}{144 \times 8 \times 1} \times 12 = \frac{1}{8} \left(28.5 + \frac{5.3}{12} \right) x^2$$

6.07 ft.

$$\text{Fig. 13, } f = \frac{26.7 \times x^2 \times 6}{12 \times 8 \times 1} \times 12 + \frac{13.3 \times x^2 \times 6}{144 \times 8 \times 1} \times 12$$

$$\therefore 800 = \frac{1}{8} \left(26.7 + \frac{13.3}{12} \right) x^2$$

Or $x = 6.19$ ft.

Jack rafters might be spaced 6 ft. apart, but for practical reasons they are spaced $4\frac{1}{2}$ = 4'-8" apart, centers.

Jack-Rafters (yellow pine).—The unsupported length = panel length $26^\circ-34' = 9 \times 1.118 = 10$ ft. The jack-rafter must resist the maximum normal forces on roof, which are 17.8 + 8.0 = 25.8 lbs. per square ft. (wind acting—no snow load), + the normal component of the weight of the jack rafter itself. Neglecting the latter for the moment, we have, W = total normal load = $28.5 \times 4\frac{1}{2} \times 10$, and bending

$$= 28.5 \times \frac{14}{3} \times \frac{10 \times 10 \times 12}{8} = \frac{1}{8} f b d^2$$

f = allowable fiber stress per sq. in. = 1300 lbs.,

b = breadth of rafter in inches,

d = depth of rafter in inches;

$$\frac{6 M_b}{f} = \frac{6 \times 28.5}{1300} \cdot \frac{14}{3} \cdot \frac{100 \times 12}{8} = 92.1.$$

$d = 6$, $b = 2.56$; hence use rafters size 3" x 6" to allow liberally for weight of rafter itself. At 4 lbs. per ft. B. M., weight of jack rafter = 6 lbs. normal component = 5.4 lbs.; tangential component = 2.7 lbs.

Purlins (white pine).—The span of the purlins is 14 feet, the distance center to center of trusses. They are laid horizontally, resting on the top chord joints, and hence spaced 10 ft. apart, centers. There are two concentrated loads on each purlin, namely, where the jack rafters rest, at points 4'-8" apart (Fig. 14). Let P and P' , Fig. 5, represent respectively the normal and tangential components of each of these loads on the purlin. Neglecting the weight of the purlin itself, the acting forces are:

	Wind acting.		Snow acting.	
	P	P'	P	P'
Wind.....	831	...	747	373
Snow.....	...	...	747	373
Slate.....	373	187	373	187
Sheathing....	126	63	126	63
Jack-rafters..	54	27	54	27
Total, lbs..	1384	277	1300	650

Fig. 14.

Fig. 15.—Purlin.

Assuming the allowable outer fiber stress $f = 1200$ lbs. per sq. in. at a and b , and the condition "snow-acting" for maximum, we have:

For $7'' \times 10''$, $f = \frac{1300 \times 14 \times 12 \times 6}{7 \times 3 \times 10 \times 10} + \frac{650 \times 14 \times 12 \times 6}{10 \times 3 \times 7 \times 7} = 1070$ lbs.; therefore

use purlins $7'' \times 10''$, which allows liberally for weight of purlins themselves. At 3 lbs. per ft. B. M. these will weigh $17\frac{1}{2}$ lbs. per lin. ft.

Trusses.—The trusses are designed for the following Cases, *considering only the members in the left hand half of the symmetrical truss:*

- Case I.—Dead load over all.
- Case II.—Snow load over all.
- Case III.—Snow load on right half only.
- Case IV.—Snow load on left half only.
- Case V.—Wind on left; left end "fixed."
- Case VI.—Wind on left; left end "roller."
- Case VII.—Wind on right; left end "fixed."
- Case VIII.—Wind on right; left end "roller."

For maximum stresses—

- Combine I with II.
- " I with VI or VII.
- " I and III with V or VI.
- " I and IV with VII or VIII.

Assuming the weight of the truss at 60 lbs. per lin. ft., the loads per joint of truss, for calculating stresses, are as follows:

Dead load per joint.—Slate, felt and sheathing, $12 \times 14 \times 10 = 1680$ lbs.; jack-rafters, $3 \times 6 \times 10 = 180$ lbs.; purlins, $14 \times 17\frac{1}{2} = 245$ lbs.; truss 540 lbs.; total, 2645 lbs.

Snow load per joint (vertical).— $20 \times 14 \times 9 = 2520$ lbs.

Wind load per joint (normal).— $17.8 \times 14 \times 10 = 2492$ lbs.

Table 12, following page, gives a summary of the stresses.

Remarks.—The preceding principles used in the design of jack-rafters, purlins, trusses, etc., of the combination truss, can readily be applied to the design of steel roofs.

For weight of steel trusses and purlins, see pages 810 and 811.

Details of Design.—Before leaving the subject of the design for combination roof truss, three points in the details of design will be considered, namely, (a) the center lower chord splice, (b) the end corbel, and (c) the center lower chord block.

(a).—The writer can conceive of no case in practice where the tensile strength of a full main wooden member is used in proportioning that member in tension. But in the case of a splice, as shown in Fig. 17, the tensile strength of the *net sections* of main member and of splice have to be considered, as well as the shearing values along the grain, and the end fiber bearing values. Fig. 17 is the splice designed for center of roof truss shown in Fig. 16.

Fig. 17.—Bottom Chord Splice. (Tension 26,000 lbs.)

Data.	Yellow pine.	Oak.
Shearing along grain, lbs. per sq. in.	100	130
Bearing.....	1500	1500
Tension.....	1500	1500

For shear: Oak keys, $a = \frac{26000}{2 \times 8 \times 130} = 13"$; Yellow pine, $b = \frac{26000}{2 \times 8 \times 100} = 17"$.

For bearing: $c = \frac{26000}{2 \times 8 \times 1500} = 1\frac{1}{4}"$; call $1\frac{1}{2}"$.

For tension: Oak keys, $o = \frac{26000}{2 \times 8 \times 1500} = 1\frac{1}{4}"$; Yellow pine, $y = 2\frac{1}{4}"$.

(b.)—Fig. 18 shows the detail at end of truss. When a corbel is used it has to be long enough to give proper shearing surface at the right of each key, while the shear on the bottom chord itself is at the left of each key. Various devices are used to resist the thrust of the rafter. In addition to the $1\frac{1}{2}"$ notch at its toe, there may be a bolt or strap $a b$ used in connection with a corbel; or a shorter bolt $a p$ without the corbel; or (still without the corbel) straps $a p$ and $p s$ may be joined by a common pin p .

Fig. 18.

(c.)—Detail of lower chord block (cast iron) is shown in Fig. 19. Where the block is not used the lower chord is simply notched as shown in Fig. 20.

Fig. 19.

Fig. 20.

Framing Table or Table of Squares.

—For calculating lengths of roof-truss members, use Tables of Squares, Sec. 33, pages 643 to 664. (See problems on page 638.) For calculating Howe truss braces and blocks see page 635.

Weight of Steel Construction in Roofs.—Where trusses, purlins, etc., are of steel the following formulas may be used in obtaining the approximate weights prior to actual calculation:

Weight in lbs. of metal in Trusses, $\left\{ \begin{array}{l} \text{per hor. sq. ft. of roof} \end{array} \right\} = \frac{1}{5} \left(\sqrt{S} + \frac{S}{10} \right) \dots\dots\dots (1)$

Weight in lbs. of metal in Trusses, Purlins and Bracing, per hor. sq. ft. of roof..... $\left\{ \begin{array}{l} \text{With minimum} \\ \text{value of about} \\ 4 \text{ or } 5. \end{array} \right\} \dots\dots\dots (2)$

In which S = span of trusses, in feet.

Weight of Steel Trusses and Purlins.—The above formulas, (1) and (2), are, of course, only approximate.

Table 13, following, gives more exact weights of trusses and of purlins for the specified horizontal load of 50 lbs. per square foot of building.

13.—STEEL ROOFS—APPROXIMATE WEIGHT OF TRUSSES AND PURLINS.

Roof of the Standard Steel Car Co., Butler, Pa. Nov. 26, '10

47.—BUILDINGS.

Plastering.—Plastering usually consists of three coats, viz., (1) the rough or "scratch" coat which is applied directly to the wood- or metal laths; (2) the "brown" coat which is floated either on the scratch coat (the latter having previously been scratched with a comb in order to roughen it so the brown coat will adhere better), or sometimes directly on the wall; and (3) the finishing or "skim" coat which is applied to the brown coat after it has been finely scratched or roughened. The skim coat may be either "stucco" or "hard finish" (gage stuff).

(1.)—The scratch coat is composed of a mixture of slaked lime, clear river or pit sand (essentially free from salt) and cattle hair* (preferably goat or cow). These are mixed in the proportion of one part lime paste to two parts sand, with $1\frac{1}{2}$ bushels of hair to each barrel of unslaked lime. Less hair is required for walls than for ceilings. A barrel of Rockland, Me., lime weighs 220 lbs. net, contains about $3\frac{1}{2}$ cubic feet, and will make about 2.6 barrels or 9 cubic feet of paste. A barrel of 200 lbs. will make about 8 cubic feet of paste. Approximately, 9 cubic feet of lime paste, 18 cubic feet of sand and 4 bushels of hair will cover 40 square yards about $\frac{1}{2}$ " thick on wooden laths (Fig. 1), and about 30 square yards on metal laths.

Fig. 1.

(2.)—The brown coat is sometimes leaner in cement than the scratch coat and contains usually but half the quantity of hair. It is generally $\frac{1}{2}$ " thick, sometimes $\frac{3}{4}$ ". Plaster prepared in sheets and shipped ready for nailing is a common substitute for the scratch and brown coats.

(3.)—The skim coat, usually $\frac{1}{4}$ ", contains no hair. Stucco is composed of one part pure lime and two parts clear sand of the purest kind, white preferred. Hard finish is made from any of the patent plasters on the market. They are composed principally of plaster of Paris or gypsum, which gives the hard finish, and are recommended for general use, being more satisfactory in many ways than the ordinary lime mixture. A mixture of $2\frac{1}{2}$ cubic feet each of lime, plaster of Paris and white sand or marble dust will skim-coat about 100 square yards from $\frac{1}{8}$ " to $\frac{1}{4}$ " thick.

Lathing and plastering is commonly estimated to weigh about 10 lbs. per square foot.

Lathing.—These may be of wood or metal. Wooden laths are usually $1\frac{1}{2}$ " wide, $\frac{1}{2}$ " thick and 4 ft. long. They are made of pine, spruce or hemlock. The straight-grained split lath is preferable to the sawed. A bundle of 100 laths (50 sq. ft., solid— $12\frac{1}{2}$ ft. B. M.— $37\frac{1}{2}$ lbs.),

spaced $\frac{1}{2}$ inch, will cover 6.48 sq. yds.: equal to 1543 laths per 100 sq. yds.	
" " " " 6.94 " " " " 1441 " " "	
" " " " 7.41 " " " " 1350 " " "	

About 10 lbs. of nails are required per 100 sq. yds. of lathing. From the above it is to be noted that lathing weighs about $\frac{1}{2}$ lb. per square foot in place.

Metal lathing, either wire or expanded metal (see Figs. 7 to 10), is now universally used in fire-proof buildings. The weight ranges from $2\frac{1}{2}$ to 4 lbs. per sq. yd., or $\frac{1}{2}$ to $\frac{3}{4}$ lbs. per sq. ft. Generally, the weight of the expanded metal per unit of area is about one-half or less than the weight of the original sheet, or, in other words, a sheet is expanded so as to cover twice or more its original area, depending upon the mesh. Thus, Diamond gage 24 covers 2.2; gage 26 covers 2.4; "A" gage 24 covers 1.9; "B" gage 27 covers 2.06, etc. 10 lbs. of staples will fasten 100 sq. yds. of expanded metal lathing.

Partitions are either permanent (fixed) or temporary (movable). In addition to the ordinary wooden partition, hollow tile and expanded metal are very largely used.

* Wood fiber is often used instead of hair, for cheap work.

Wooden Partitions.—Fig. 2 represents the average partition used in a frame dwelling. The studding is spaced 16 ins. on centers. It will be noted that those pieces marked with a cross (X) would be superfluous if the door opening were omitted: *a, c, c* would complete the studding, and *b* the

Fig. 2.—Stud Partition; dimension stuff either all 2"x 6" or all 2"x 4".

bridging, across the door opening. In the above illustration, about 26½ lineal feet of extra scantling is required for each door opening, over that for a plain partition. A partition of this kind will weigh 3 or 4 lbs. per square foot, exclusive of laths and plaster.

Hollow-Tile Partitions.—Solid terra cotta weighs from 120 to 125 lbs. per cubic foot, 122½ lbs. being a good average; but the hollow blocks for partitions will usually not exceed two-thirds that amount, and may weigh somewhat less. The following types of blocks are used:

Fig. 3.—Plain Hollow Block.

Fig. 4.—Webbed Block.

Fig. 5.—Patent Block for plastering.

Figs. 3 and 4 are ordinary blocks such as are used in a partition with I-beam studding (see Fig. 6). The patent blocks illustrated in Fig. 5 are sustained laterally by means of horizontal metal strips or bands of steel between vertical studding.

Other Partitions than the hollow tile which may be used in connection with I-beam studding (Fig. 6) are (a) plaster boards, which are laid in between the beams and flushed for plastering; (b) wire lathing strung between the beams flush with the flanges and fastened to them, and also supported intermediately with angles about 2-ft. centers; (c) expanded metal lathing.

Fig. 6.—Ordinary Hollow-tile wall with steel I-beam studs.

These three classes of material may also be used with other skeleton designs, provided the principle of rigidity is maintained. Figs. 7 and 8 are examples of hollow and of solid partition construction by the expanded metal system, and Figs. 9 and 10 are cuts of the metal lath used. The lathing can be plastered with ordinary lime plaster, but cement plaster is better.

"B" Lath.
27 Gage. Sheets, 18 ins. x 96 ins. 20 sq. yds. per bundle.

Floors, Ceilings, etc.—The following loads are considered in designing the floors of buildings:

(1.) Live loads, due to—

- (a) People;
- (b) Safes, merchandise, furniture, machinery, etc.;
- (c) Partitions which are subject to change of position.

(2.) Dead loads, due to—

- (d) Flooring or tiling;
- (e) Fireproof arches between the beams;
- (f) Ceiling, under the floor;
- (g) Beams directly supporting the above;
- (h) Girders, supporting the beams and in turn directly supported by the columns or walls.

Live Loads.—There is great diversity of opinion among engineers regarding the live loads to be assumed for each class of buildings, and this is aggravated by the decided lack of harmony of the various city building codes. For instance, the requirements of the ten leading cities of the United States are shown in the following table:

1.—MINIMUM LIVE LOADS FOR FLOORS AND ROOFS—TEN LEADING CITIES.

¶ For flat roofs.

It has been found by actual test that forty selected men with an average weight of 163.2 lbs. may be packed into a floor area of 6-ft. square, when each man tries to occupy as little space as possible. This is equivalent to an occupied area of $\frac{1}{4}$ of a sq. ft. per man, an average load of 181.3 lbs. per sq. ft. of floor, and a total load of 6528 lbs. Perhaps the passenger elevator would instance a load approaching the above ideal more closely than would any other case in practice, but even there a load of 120 lbs. per sq. ft. makes a very compact and uncomfortable mass, and is probably very rarely obtained. For a "mixed" crowd covering a considerable area as in public halls or corridors, 100 lbs. per sq. ft. may be taken as the extreme loading, even when the ordinary crowding takes place. People in a crowd do not stand perfectly erect and allow themselves to be packed together as in the ideal case above cited. Occasionally during a panic the people in the center of a crowd may be packed so as to produce a concentrated loading nearly equivalent to the ideal load of 180 lbs. per sq. ft. over a limited area, but by

no means over the whole floor space or even over any considerable portion of it. Hence in designing floors where people congregate it is good practice to adopt heavier loadings for small floor areas in a building than for large ones. In other words the live load per sq. ft. of floor area may be allowed to decrease, in tall buildings, from the maximum loading for floor beams and arches, down to the minimum for columns and foundations—main girders taking an intermediate position.

Loads from Safes.—One of the most important factors to be considered in the design of floors for office buildings and offices in general is the effect due to the weight of safes. Hence the following table is inserted as comprising the heaviest safes in use (the 900's and 800's) and also those commonly used for upper floor offices (the 500's). Numbers "A", "B" and "C" are very heavy compared with their dimensions and are liable to be placed in any office. The 600's and 700's, omitted in this table, range in weight between the 500's and 800's. The 2500-lb. safe, No. 513, is the lightest one considered. For any desired calculation columns 6 and 7, showing the distance apart of the supporting wheels, may be used in connection with either column 8, or with column 2 in connection with 10, 11 or any other assumed weight of the contents of the safe. In general, the use of column 8 is considered good practice.

2.—TABLE OF WEIGHTS AND DIMENSIONS OF HEAVY SAFES.

Fixed Vaults with their contents may be considered as static loads and must be specially considered, but Movable Safes are liable to be placed in almost any position on the floor.

Problem 1.—On the first floor of a building find what single concentrated load will give the same bending moment as safe No. 921, Table 2, to one of a system of parallel beams spaced 5 ft. centers and 16 ft. long?

Solution.—Let *A*, *B* and *C*, Fig. 11, represent the beams of which *B* is the one under consideration; *D* and *E* the supporting girders; and 1, 2, 3 and 4 the four wheels supporting the safe, of which *c* is the center. From the principle of the maximum floor-beam reaction, page 692, *B* will support the greatest load when it bisects the normal distance between the center of gravity *c* and the line 1-2; that is, with maximum resultant at *r*. Likewise, the maximum moment on *B* will obtain at *m*, equidistant with *r* from the line *Y-Y* which bisects the beams. If each of the corner weights of the safe is 4422 lbs., we have, for resultant at *r*, on beam *B*,

$$r = 8844 \left(\frac{10 - 2.7}{5} \right) = 12912 \text{ lbs.},$$

and maximum moment, at *m*, $= \frac{r}{16} (8 - 1.175)^2$.

The moment due to a load *P* at the center of the beam $= \frac{P}{2} \times 8$; whence, equating with the above,

$$\frac{P}{2} \times 8 = \frac{r}{16} (6.825)^2 \text{ or } P = .7278 r = 9400 \text{ lbs.}$$

Hence, in the above case it will be noted that a concentrated load of 9400 lbs. applied at the center of the beam *B* will produce a bending moment equal to that of the safe weighing 17,688 lbs., placed *rectangularly* in the most critical position. Furthermore, this is equivalent to a running load of 1175 lbs. per lineal foot of beam, or to a distributed load of 235 lbs. per square foot of floor. If safe is placed *diagonally* on beam, the bending moment will be increased about 5 per cent.

EXAMPLES OF FLOOR AND CEILING CONSTRUCTION.

Fig. 12.—Floor Framing.—*a* is a double hanger or stirrup; *b* is a patent hanger; *c* is a common mortise.

The under flooring may be spruce or hemlock, $\frac{1}{2}$ " thick and laid diagonally in order to brace or stiffen the floor. On top of this and at right angle with the tail beams is laid the finished flooring which may be white pine $\frac{1}{2}$ " thick or any other flooring material. The ceiling may consist of lathing and plastering below the beams in the usual manner.

Fig. 13.—Centering for Brick Arch.

Fig. 14.—4-inch Brick Arch.—*c* is wooden screed on which is nailed the rod; *w*, washer; *a*, angle iron thrust of the arch; *I*, steel beam.

Fig. 15.—Hollow Bricks.

Fig. 16.—Skew-back.

Instead of the solid bricks, hollow bricks are often used to reduce the dead load of the arch. Figs. 15 and 16 are examples of hollow bricks and skew-backs. They can be manufactured in any pattern.

DIGEST OF THE NEW YORK CITY BUILDING CODE (1906).

[Also District of Columbia, practically the same.]

QUALITY OF MATERIALS.

1. **Lime mortar.**—1 part lime, not > 4 parts sand; lime properly slaked before being mixed with the sand.
2. **Cement mortar.**—1 part cement, not > 3 parts sand; mixed before adding water. *Portland cement*—cement that, when tested neat, will resist tension of at least 120 lbs. per sq. in., after 1 day air setting; and 300 lbs., after 1 day in air and 6 days in water. *Other cements*, 60 lbs. and 120 lbs., respectively.
3. **Cement and lime mortar.**—1 part cement, 1 part lime, not > 3 parts of sand to each.
4. **Concrete.**—At least 1 cement; 2 sand; 5 clean broken stone (2 in. ring), or 5 clean gravel.
5. **Wrought iron.**—Ultimate strength 48,000 lbs. per sq. in.; elastic limit not < 24,000; elongation 20% in 8 ins. (small specimens).
6. **Steel.**—Ult str, 54–64,000; elastic limit, not < 32,000; elongation, not < 0.20. Rivet steel, 50–58,000 ult str.
7. **Cast iron.**—One-inch square bar, 54-in. span, shall support central load of 450 lbs. before breaking. Tensile strength, not < 16,000 lbs. per sq. in. (small specimens).

EXCAVATIONS AND FOUNDATIONS.

8. **Bearing capacity of soil.**—Where no tests are made allow for soft clay, 1 ton per sq. ft.; ordinary clay and sand together, in layers, wet and springy, 2 tons; loam, clay or fine sand, firm and dry, 3 tons; very firm, coarse sand, stiff gravel or hard clay, 4 tons.
9. **Pressure under footings of foundations.**—For warehouses and factories, full dead and full live loads; for stores, light factories, churches, school houses, and places of public amusement or assembly, full dead and 75 per cent of live loads; for office buildings, hotels, dwellings, apartment houses, tenement houses, lodging houses, and stables, full dead load and 60% of live load.
10. **Foundations.**—Piles 20 ft. or less in length, not < 5 ins. at small end and 10 ins. at butt. Piles over 20 ft., not < 12 ins. at butt. Max load per pile 40,000 lbs. Use Engineering News formula when pile is not driven to refusal: $P = \frac{2wh^*}{s+1}$. Safe load for stone, brick or concrete piers in caissons: to rock, not > 15 tons per sq. ft.; to firm gravel or hard clay, 10 tons; in open caissons or sheet pile trenches, 8 tons.

WOODEN BEAMS, GIRDERS AND COLUMNS.

11. **Wood beams.**—Minimum thickness, 3 ins. Every wood header or trimmer more than 4 ft. long shall be hung in stirrup irons. All wood floor and wood roof beams bridged with cross bridging spaced not > 8 ft. Safe uniform load in lbs. per lineal foot for long spans: hemlock, $70 \frac{bd^2}{L}$; spruce and white pine, $90 \frac{bd^2}{L}$; oak, $120 \frac{bd^2}{L}$; yellow pine, $140 \frac{bd^2}{L}$; in which b = breadth of beam in inches., d = depth in ins., L = length in ft. For short spans the shear must be considered.

12. **Timber for trusses.**—Working stresses in timber struts of pin-connected trusses shall not exceed 75% of the working stresses established in ar. 27–30.

FIREPROOF BUILDINGS.

13. **Fireproof buildings.**—For buildings exceeding 12 stories or 150 ft. the floors shall be of stone, cement, rock asphalt, tiling, etc., or the sleepers and floors may be of wood treated by some approved process to render them reproof.

14. Fireproof floors.—Shall be constructed with wrought iron or steel floor beams calculated to deflect no more than $\frac{1}{8}$ -inch per foot of span under total (live and dead) load; and tie rods shall be spaced not > 8 times depth of beam. (1) Brick arches, springing from the lower flange of the steel beams, shall be designed with a rise not $< 1\frac{1}{2}$ ins. for each foot of span, and with a thickness not < 4 ins. for spans of 5 ft. or less, and not < 8 ins. for spans over 5 ft. They shall be composed of good hard brick or hollow brick of ordinary dimensions laid to a line on the centers, properly and solidly bonded, each longitudinal line of brick breaking joints with the adjoining lines in the same ring and with the ring under it when more than 4-in. arch is used; cement mortar joints. (2) Hollow tile arches of hard-burned clay or porous terra-cotta shall have an effective depth not $< 1\frac{1}{2}$ ins. per ft. of span, some allowance (not over 6 ins.) being made if soffit of arch is straight; if segmental, the depth of tile shall be not < 6 ins. if rise is not $< 1\frac{1}{2}$ ins. times span in ft.; cement mortar joints. (3) Portland cement concrete arches, segmental, with rise not $< 1\frac{1}{2}$ ins. times span in ft. Thickness at crown not < 4 ins. Mixed as per par. 4. Arches shall be reinforced and protected on under side with corrugated or sheet steel, steel ribs, or metal in other forms weighing not less than 1 lb. per sq. ft., and having no openings larger than 3 sq. ins. (4) Reinforced floors of solid or hollow burned clay, stone, brick, or concrete slabs in flat or curved shapes, in combination with wire cloth, expanded metal, wire strands, or wrought iron or steel bars, may be used, but proper tests shall be made as provided in the Code.

IRON AND STEEL CONSTRUCTION.

15. Skeleton construction.—Where columns are used to support iron or steel girders carrying inclosure walls, the said columns shall be of cast iron, wrought iron, or rolled steel, and on their exposed outer and inner surfaces be constructed to resist fire by having a casing of brickwork not less than 8 ins. thick on the outer surfaces, nor less than 4 ins. thick on the inner surfaces, all bonded into the brickwork of the inclosure walls. Exposed sides of girders protected with 4 ins. of brickwork; outer edges of flanges, 2 ins.

16. Steel and wrought iron columns.—Minimum thickness of metal, $\frac{1}{2}$ inch. Least lateral dimension $\frac{1}{16}$ length of column, except as allowed in par. 26.

17. Cast iron columns.—Minimum diameter, 5 ins.; minimum thickness of metal, $\frac{1}{2}$ in. Least lateral dimension $\frac{1}{16}$ length of column, except as allowed in par. 26.

18. Steel and iron girders.—Stiffeners shall be used at intervals not exceeding 120 times thickness of web if the unsupported depth of the web plate exceeds 60 times its thickness.

19. Rolled beams used as girders.—Beams in pairs to form girders shall be connected together by bolts and separators at intervals of not more than 5 ft. Beams 12 ins. or more in depth shall have 2 bolts to each separator.

20. Cast iron lintels.—Maximum span, 16 ft.; minimum thickness of metal, $\frac{1}{2}$ in.

21. Painting of structural metal work.—After erection all work shall be painted at least one additional coat. All iron or steel used under water shall be inclosed with concrete.

FLOOR LOADS.

22. Floor loads.—Dead loads—weight of walls, floors, roofs, partitions and all permanent construction. Live loads—variable loads—all loads other than dead loads. Live loads per sq. ft. of floor shall be assumed as follows:

For dwelling, apartment, tenement, hotel or lodging house, not < 60 lbs.	
For office purpose, first floor, - - - - -	75 "
all floors above the first, - - - - -	150 "
school or place of instruction, - - - - -	75 "
stable and carriage house purposes, - - - - -	75 "
place of public assembly, - - - - -	90 "
ordinary stores, light manufacturing, light storage, - - - - -	120 "
warehouse, factory, heavy stores, - - - - -	150 "
roofs with pitch less than 20° , per area of roof, - - - - -	50 "
" more " 20° , per horizontal area, - - - - -	30 "
sidewalks, between the curb and area lines, - - - - -	100 "

For the purpose of determining the carrying capacity of columns of office buildings, stores, stables and public buildings when over height, a reduction of the live loads shall be permissible as follows: the roof and top floor the full live loads shall be used; for each lower floor it shall be permissible to reduce the live load by 5% if the live loads fixed by this section is reached, when such reduction shall be used for all remaining floors.

CALCULATIONS.—STRENGTH OF MATERIALS.

Safe load for masonry work.—Safe load per sq. ft.: Brickwork in lime and cement mortar mixed, 23,000 lbs.; in Portland cement, 20,000 lbs.; Rubble-stone work in Portland cement, 20,000 lbs.; in lime and cement mixed, 14,000 lbs.; Portland cement concrete, 30,000 lbs. Other concrete, 16,000 lbs.

Weights of certain materials.—In computing weight of walls, one cubic foot of brickwork shall be deemed to weigh 115 lbs.; sandstone, white granite and other kinds of building stone, 170 lbs. per cubic foot.

Factors of safety.—While working stresses are not prescribed for metals, 6 for timber, 10 for natural or artificial stones and brick masonry.

Strength of columns.—Safe load in lbs. per sq. in.: Cast iron, 15,000; steel, $15,200 - 58 \frac{l}{r}$; wrought iron, $14,000 - 80 \frac{l}{r}$. Yellow

pine (leaf), $1000 - 18 \frac{l}{d}$; white pine, Norway pine, spruce, $800 - 15 \frac{l}{d}$;

chestnut and hemlock, $\frac{5}{8} \left(800 - 15 \frac{l}{d} \right)$; locust, $\frac{3}{2} \left(800 - 15 \frac{l}{d} \right)$.

Centrically loaded shall have such stresses computed, and the stresses shall not exceed the allowable working stresses. The area of a column shall be considered to be distributed equally over the area of that column at the next point below at which the column is braced laterally in the direction of the eccentricity.

Compression (Direct).—Safe load in lbs. per sq. in.: Rolled steel, 16,000; wrought iron, 12,000; cast iron (in short blocks), 10,000; steel pins and rivets (bearing), 20,000; wrought iron pins and rivets (bearing), 15,000.

White pine,	- 40	250	Hemlock,	- 40	275
Spruce,	- 50	320	Chestnut,	- ...	150
Oak, - - -	100	600			

30. **Bending.**—Safe extreme fiber stress in lbs. per sq. in.: Rolled beams, Steel, 16,000; wrought iron, 12,000. Rolled pins, rivets and bolts: Steel, 20,000; wrought iron, 15,000. Riveted beams (not flange section): Steel, 14,000; wrought iron, 12,000. Cast iron: Compression side, 16,000; tension side, 3,000. Yellow pine, 1,200; white pine, spruce, 800; oak, 1,000; locust, 1,200; hemlock, 600; chestnut, 800. Granite, 180; Greenwich stone, 150; gneiss (New York City), 150; limestone, 150; slate, 400; marble, 120; sandstone, 100; bluestone (North River), 300; brick (common), 50; brick-work (in cement), 30. Concrete: (Portland), 1:2:4, 30 lbs.; 1:2:5, 20 lbs.; (Rosendale, or equal), 1:2:4, 16 lbs.; 1:2:5, 10 lbs.

31. **Wind pressure.**—All structures exposed to wind shall be designed to resist a horizontal wind pressure of 30 lbs. for every sq. ft. of surface thus exposed, from the ground to the top of same, including roof, in any direction. In no case shall the overturning moment due to wind pressure exceed 75% of the moment of stability of the structure. In all structures exposed to wind, if the resisting moments of the ordinary materials of construction such as masonry, partitions, floors and connections are not sufficient to resist the moment of distortion due to wind pressure, taken in any direction on any part of the structure, additional bracing shall be introduced sufficient to make up the difference in the moments. In calculations for wind bracing, the working stresses set forth above may be increased by 50%. In buildings under 100 ft. high, where the height does not exceed four times the average width of the base, the wind pressure may be disregarded.

CONCRETE-STEEL CONSTRUCTION.

1. The term "concrete-steel" shall mean an approved concrete mixture reinforced by steel of any shape, the steel to take up the tensional stresses and assist in the resistance to shear.

2. Concrete-steel construction will be approved only for buildings which are not required to be fireproof by the building code, unless satisfactory fire and water tests shall have been made under the supervision of this bureau.

3. Complete drawings and specifications must be filed with the supt. of buildings, showing all details of the construction, the size and position of all reinforcing rods, stirrups, etc., and giving the composition of the concrete.

4. Execution of work shall be under the control of a competent foreman or superintendent.

5. Concrete to be mixed in the proportions of 1 cement, 2 sand, and 4 stone or gravel; or the proportions may be such that the resistance of the concrete to crushing shall not be less than 2000 lbs. per sq. in. after hardening for 28 days. The concrete is to be what is usually known as a "wet" mixture.

6. Only high-grade Portland cements shall be permitted; and shall develop a tensile strength of at least 300 lbs. per sq. in. after 1 day in water; at least 500 lbs. per sq. in. after 1 day in air and 6 days in water; and at least 600 lbs. per sq. in. after 1 day in air and 27 days in water.

7. The sand must be clean and sharp, free from loam or dirt, and not finer than the standard sample submitted.

8. The stone shall be clean, broken trap rock, or gravel, of a size that will pass through a three-quarter inch ring.

9. The steel shall have an ult. str. of 54-64,000 lbs. per sq. in.; an elastic limit of not less than 32,000 lbs. per sq. in.; and a min. elong. of not less than 20% in 8 ins.

concrete-steel design the following stresses in lbs. per square foot be exceeded:

Stress on concrete in compression.....	500 (650*)
Stress in concrete.....	50
Direct compression.....	350 (450*)
Stress in steel.....	16,000
Stress in steel.....	10,000

Adhesion of concrete to steel shall be assumed to be not greater than the safe working strength of the concrete.

Ratio of modulus of elasticity of concrete and steel shall be not less than 12.

The following assumptions shall guide in the determination of the stresses due to the external forces: (a) Beams and girders shall be designed as simply supported at the ends, no allowance being made for over supports. (b) Floor plates, when constructed continuous and provided with reinforcement at top of plate over the supports, shall be designed as continuous beams, the bending moment for uniformly loaded beams being taken at not less than $WL+10$; the bending moment shall be taken as $WL+20$ in the case of square floor plates which are reinforced in all directions and supported on all sides. The floor plates to the extent more than ten times the width of any beam or girder may be treated as part of that beam or girder in computing its moment of resistance. In calculating the moment of resistance it is assumed that the stress in the fiber is directly proportional to its distance from the neutral axis. In considering the proportionate moduli of elasticity of concrete and steel (c) The tensile strength of the concrete shall not be con-

sidered in the shearing stresses developed in any part of a concrete-steel design exceed the safe working strength of concrete, a sufficient reinforcement shall be introduced in such a position that the deficiency in concrete to shear is overcome.

The safe limit of adhesion between the concrete and steel is assumed to be the provision must be made for transmitting the strength of the concrete.

Concrete-steel may be used for columns in which the ratio of length to diameter does not exceed 12. The reinforcing rods must be spaced at intervals of not more than the least side or dia. of column.

The contractor must be prepared to make load tests on any portion of concrete-steel construction, within a reasonable time after erection, as required by the supt. of buildings. The tests must show that the construction will sustain a load of 3 times that for which it is designed at any sign of failure.

ACT FROM CHICAGO BUILDING ORDINANCE (1910).

REINFORCED CONCRETE.

Moduli of Elasticity—Adhesion—Bond.—(a) The calculations of the strength of reinforced concrete shall be based on the assumed ultimate strength U , in pounds per square inch, given in the table below for the mixture to be used. (b) The ratio of the modulus of elasticity of steel to that of concrete is designated by the letter R :

1 part cement, 1 sand, 2 broken stone, gravel or slag	$U=2,900$; $R=10$.
1 part cement, 1½ sand, 3 broken stone, gravel or slag	$U=2,400$; $R=12$.
1 part cement, 2 sand, 4 broken stone, gravel or slag	$U=2,000$; $R=15$.
1 part cement, 2½ sand, 5 broken stone, gravel or slag	$U=1,750$; $R=18$.
1 part cement, 3 sand, 7 broken stone, gravel or slag	$U=1,500$; $R=20$.

Mr. J. H. Saynor's views expressed under date of July 21, 1911, regarding the proposed revised code. He also says: As near as I can make out from the explanation given to me the cost of cinder concrete should not be considered as not necessary that the cinders should be screened. The weight of the arches should not be increased from the minimum of $4\frac{1}{2}$ to $6\frac{1}{2}$. That is unnecessary. The weight of the reinforcing steel should not be raised to a minimum of one pound per square foot. A quarter of a pound per square foot may suffice. A precise and accurate standard should be made to govern.

Adhesion—Bond.—For a concrete of 1:2:4 mix, the allowable adhesion in lbs. per sq. in. of surface of embedment shall not exceed the following: On plain bars of structural steel, 70; on plain bars of high carbon steel, 50; on plain flat bars in which width to thickness is not >2 to 1, 50; on twisted bars when twisting is not $<$ one complete twist in eight diameters, 100.

EXTRACT FROM BUILDING LAWS AND ORDINANCES OF PHILADELPHIA (1907).

Live Loads for Floors.—*Lbs. per sq. ft.*: Dwellings, tenement houses, apartment houses, hotels, hospitals and asylums, 70 lbs.; office buildings, 100 lbs.; places of public assembly, light manufacturing and retail stores, 120 lbs.; storehouses, warehouses and manufactories, 150 lbs. and upward in proportion to the loads they have to carry.

Roofs shall be constructed to bear a safe weight of 30 lbs. per superficial foot.

Ultimate Stresses in lbs. per sq. in.:

	Cast Iron.	Wrt. Iron.	Mild Steel.	Medium Steel.	Hemlock.	Spruce	Long Leaf Yellow Pine.
Tension (direct).....		50,000	58,000	65,000	4,000	5,000	7,200
Compression (direct)....	70,000	50,000	58,000	65,000	2,100	3,000	4,500
Bending—extreme fiber (tension).....	15,000				3,600	4,400	6,400
Shear.....		30,000	35,000	40,000			
Shear—perp. to grain.....					2,500	3,000	4,500
Shear—parallel with grain.....					250	300	400

Working Stresses* in lbs. per sq. in.:

	Cast Iron.	Wrt. Iron.	Mild Steel.	Medium Steel.	Hemlock.	Spruce	Long Leaf Yellow Pine.
Tension.....		12,500	14,500	16,250	1,000	1,250	1,800
Compression.....	11,667	12,500	14,500	16,250	350	500	750
Compression—perp. to grain.....					250	300	550
Bending—extreme fiber (tension).....	3,750				900	1,100	1,600
Shear.....		7,500	8,750	10,000			
Shear—perp. to grain.....					416	500	750
Shear—parallel to grain.....					41	50	66

* For columns, the safe working loads p in lbs. per sq. in. may be reduced by the following formulas:—

$$\text{Cast iron, } p = \frac{11667}{1 + \frac{400l^2}{r^2}}; \quad \text{Wrought iron, } p = \frac{12500}{1 + \frac{15000l^2}{r^2}};$$

$$\text{Mild steel, } p = \frac{14500}{1 + \frac{13500l^2}{r^2}}; \quad \text{Medium steel, } p = \frac{16250}{1 + \frac{11000l^2}{r^2}};$$

Hemlock, $p = 350 - 3.5 \frac{l}{d}$; Spruce, $p = 500 - 5 \frac{l}{d}$; Yellow pine, $p = 750 - 7.5 \frac{l}{d}$.

In which l = length, r = least radius of gyration, d = least diameter, all in inches. The allowable reduction of live load on columns and girders shall be as follows: "For all tenement houses, hotels, apartment houses, hospitals and office buildings the live loads on columns, girders and foundations may be estimated by the formula $X = 100 - \frac{1}{4} \sqrt{A}$, and for light manufacturing buildings by the formula $X = 100 - \frac{1}{3} \sqrt{A}$, in which "X" equals the percentage of live load to be used, and "A" equals area carried by any girder, column or foundation.

Allowable Pressures in lbs. per sq. ft.—Concrete, 15 tons; brickwork in lime mortar, 8 tons; brickwork in lime and cement mortar, 12 tons; brickwork in cement mortar, 15 tons; stonework (rubble) in lime mortar, 5 tons; stonework (rubble) in lime and cement mortar, 8 tons; stonework (rubble) in cement mortar, 10 tons.

Reinforced Concrete.—Reinforced concrete construction will be accepted for fireproof buildings of the first class, if designed as hereinafter prescribed; provided, that the aggregate for such concrete shall be clean broken hard stone, or clean graded gravel, together with clean siliceous sand or fine grained gravel; should the concrete be used for flooring between rolled steel beams, clean furnace clinkers entirely free of combustible matter, or suitable seasoned furnace slag may be used; when stone is used with sand or gravel it must be of a size to pass through a one-inch ring, and 25% of the whole must not be more than one-half the maximum size; and provided further, that the minimum thickness of concrete surrounding the reinforcing members of reinforced concrete beams and girders shall be 2 ins. on the bottom and one-half inch on the sides of said beams and girders. The minimum thickness of concrete under slab rods shall be one inch. All reinforcement in columns to have a minimum protection of 2 ins. of concrete.

For walls, reinforced concrete may be used in place of brick and stone walls, in which case the thickness may be two-thirds of that required for brick walls. Concrete walls in such cases must be reinforced in both directions in an approved manner.

All steel reinforcement shall be of standard grade of structural steel or iron of either grade to meet the "Manufacturers' Standard Specifications," revised Feb. 3, 1903.

Slabs, beams and girders shall be designed on the assumption of a load four times as great as the total load (ordinary dead load plus ordinary live load). The steel to take all the tensile stresses. The stress-strain curve of concrete in compression is a straight line.

Ratio of moduli of elasticity of concrete to steel: Stone or gravel concrete, 1 to 12; slag concrete, 1 to 15; cinder concrete, 1 to 30.

Allowable unit transverse stress (lbs. per sq. in.) upon concrete in compression: Stone or gravel concrete, 600; slag concrete, 400; cinder concrete, 250.

Allowable unit transverse stress (lbs. per sq. in.) in tension: Iron, 12,000; steel, 16,000.

Allowable unit shearing stress (lbs. per sq. in.) upon concrete: Stone or gravel concrete, 75; slag concrete, 50; cinder concrete, 25.

Allowable unit adhesive strength (lbs. per sq. in.) of concrete: Stone or gravel concrete, 50; slag concrete, 40; cinder concrete, 15.

Allowable unit stresses (lbs. per sq. in.) upon concrete in direct compression in columns: Stone or gravel concrete, 500; slag concrete, 300; cinder concrete, 150.

Allowable unit stress upon hoop columns composed of stone or gravel concrete shall not be over 1000 lbs. per sq. in., figuring the net area of the circle within the hooping. The percentage of longitudinal rods and the spacing of the hoops to be such as to permit the concrete to safely develop the above unit stress with a factor of safety of 4.

Floor slabs, when constructed continuously, and when provided with reinforcement at top of slab over the supports, may be treated as continuous beams, the bending moment for uniformly distributed loads being taken at not less than $WL + 10$. In case of square floor slabs which are reinforced in both directions and supported on all sides, the bending moment may be taken at $WL + 20$; provided, that in floor slabs in juxtaposition to the walls of the building the bending moment shall be considered as $WL + 8$, when reinforced in one direction, and if the floor slab is square and reinforced in both directions the bending moment shall be taken as $WL + 16$.

In columns the longitudinal rods will not be considered as taking any direct compression.

EXTRACT FROM THE BUILDING LAW OF BOSTON (1909).

MATERIALS—ALLOWABLE FIBER STRESSES.

[Lbs. per square inch.]

Timber.—Extreme fiber (bending): White pine and spruce, 1000; white oak, 1000; yellow pine (long leaf), 1500. Shearing along grain: White pine, 0; white oak, 150; yellow pine (long leaf), 100. Compression perpendicular to grain: White pine and spruce, 250; white oak, 600; yellow pine (long leaf), 00. Modulus of elasticity: White pine, 750,000; spruce, 900,000; white oak,

850,000; yellow pine (long leaf), 1,300,000. Columns (centrally loaded and flat ends): White pine and spruce, 630 for $L+D=0$ to 10, 595 for $L+D=10$ to 15, 560 for $L+D=15$ to 20, 525 for $L+D=20$ to 25, 490 for $L+D=25$ to 30; white oak, 810 for $L+D=0$ to 10, 765 for $L+D=10$ to 15, 720 for $L+D=15$ to 20, 675 for $L+D=20$ to 25, 630 for $L+D=25$ to 30; yellow pine (long leaf), 900 for $L+D=0$ to 10, 850 for $L+D=10$ to 15, 800 for $L+D=15$ to 20, 750 for $L+D=20$ to 25, 700 for $L+D=25$ to 30. No column shall be used with greater value than $L+D=30$. For eccentric loads, see Methods of Computation, p. 827.

Wrought Iron and Steel (steel at 55-65,000).—Extreme fiber of rolled beams or shapes: Wrought iron, 12,000; steel, 16,000. Tension: Wrought iron, 12,000; steel, 16,000. Compression in flanges of built beams: Wrought iron, 12,000; steel, 16,000. Shearing (including pins and rivets, but not bolts): Wrought iron, 9,000; steel, 10,000. Shearing (bolts): 80% of preceding values. Direct bearing (including pins and rivets, but not bolts): Wrought iron, 15,000; steel, 18,000. Direct bearing (bolts): 80% of preceding values. Bending on pins: Wrought iron, 18,000; steel, 22,500. Modulus of elasticity: Wrought iron, 27,000,000; steel, 29,000,000. For compression members, use the formula: $[12,000 \text{ for iron or } 16,000 \text{ for steel}] \text{ divided by } [1 + (L^2 + 20000r^2)]$, in which L =length and r =radius of gyration in inches. Compression flanges of beams shall be proportioned to resist lateral flexure; if the ratio of unsupported length of flange to width of flange does not exceed 20, no allowance need be made; if the ratio is 70, the above specified allowable fiber stress shall be reduced by one-half; and proportionate for values between 20 and 70.

Cast Iron.—Extreme fiber stress: Tension, 8,000; compression, 16,000. Columns (centrally loaded and unsupported laterally): Average stress, 11,000 for $L+r=10$, 10,700 for $L+r=20$, 10,400 for $L+r=30$, 10,000 for $L+r=40$, 9,800 for $L+r=50$, 9,500 for $L+r=60$, 9,200 for $L+r=70$. L and r in inches. Cast iron shall not be used for columns in buildings of more than 75 feet in height, nor in cases where $L+r$ exceeds 70.

[Tons (2000 lbs.) per square foot.]

Stone Work, in Compression.—First quality dressed beds and builds, laid solid in mortar of one part Portland cement to three parts sand, or one part natural cement to two parts sand. Granite, 60; marble and limestone, 40; sandstone, 30. When poorer mortar is used the above stresses shall be lowered (as approved).

Brickwork, in Compression.—(1.) For first class hard-burned bricks, including piers in which the height does not exceed six times the least dimension, laid in: (a) One part Portland cement, three parts sand, by volume, dry, 20; (b) One part natural cement, two parts sand, by volume, dry, 18; (c) One part natural cement, one part lime and six parts sand, by volume, dry, 12; (d) Lime mortar, one part lime, six parts sand, by volume, dry, 8. (2.) For brick piers of hard-burned bricks, in which the height is from six to twelve times the least dimension: Mortar (a), 18; mortar (b), 15; mortar (c), 10; mortar (d), 7. (3.) For brickwork made of "light-hard" bricks, the stresses shall not exceed two-thirds of the stresses for like work of hard-burned bricks.

CONCRETE AND REINFORCED CONCRETE.

Cement shall conform to the specifications of the American Society for Testing Materials, as modified from time to time by that association.

Concrete.—When the structural use of concrete is proposed, a specification, stating the quality and proportions of materials, and the methods of mixing the same, shall be submitted to the building commissioner, who may issue a permit at his discretion and under such further conditions, in addition to those stated below, as he sees fit to impose.

A. In first class Portland cement concrete, containing one part cement to not more than six parts mixed properly graded aggregate, except in piers or columns of which the height exceeds six times the least dimension, the compressive stress shall not exceed 30 tons of 2000 lbs. per sq. ft.

B. In piers and columns of first class Portland cement concrete, containing one part cement to not more than five parts mixed properly graded aggregate, where the height of the pier or column is more than six times and does not exceed twelve times its least dimension, the compressive stress shall not exceed 25 tons of 2000 lbs. per sq. ft.

By "aggregate" shall be understood all the materials in the concrete except the cement. Cinder concrete shall be used constructively only for floors, roofs and for filling.

Rules for the computation of reinforced concrete columns may be formulated from time to time by the building commissioner with the approval of the board of appeal.

In reinforced concrete beams or slabs subjected to bending stresses, the entire tensile stress shall be assumed to be carried by the steel, which shall not be stressed above the limits allowed for this material. First class Portland cement concrete in such beams or slabs, containing one part cement to not more than five parts mixed properly graded aggregate, may be stressed in compression to not more than 500 lbs. per sq. in. In case a richer concrete is used, this stress may be increased with the approval of the commissioner to not more than 600 lbs. per sq. in.

In reinforced concrete the maximum shearing force upon the concrete, when uncombined with compression upon the same plane shall not exceed 60 lbs. per sq. in., unless the building commissioner with the consent of the board of appeal shall fix some other value.

If the embedded steel has no mechanical bond with the concrete, its holding power shall not exceed the allowable shearing strength of the concrete.

Reinforced Concrete.—Reinforced concrete slabs, beams or girders, if rendered continuous over supports by being unbroken in section, shall be provided with proper metal reinforcement at the top over said supports and may be computed as continuous beams, as hereinafter described.

The modulus of elasticity of the concrete, if not shown by direct tests, may for beams and slabs be taken as one-fifteenth that of steel, and for columns one-tenth that of steel.

The reinforcing metal shall be covered by not less than three-fourths inch of concrete in slabs, and by not less than one and one-half inches of concrete in beams and columns.

Methods of Computation.—Beams or girders of metal or reinforced concrete shall be considered as simply supported at their ends, except when they extend with unbroken cross-section over the supports, in which case they may be considered as continuous.

The span of a beam shall be considered as the distance from center to center of the bed plates or surfaces upon which it rests. If it is fastened to the side of a column, the span will be measured to the center of the column.

In slabs, beams or girders continuous over supports, provision shall be made for a negative bending moment at such supports equal to four-fifths of the positive bending moment that would exist at the center of the span if the piece were simply supported; and the positive bending moment at the center of the span may be taken equal to the negative bending moment at the support.

In the case of a slab of reinforced concrete with parallel ribs or girders beneath, the rib or girder may be considered to include a portion of the slab between the ribs, forming a T-beam. The width of the T-beam on top shall not exceed one-third of the span of the rib nor the distance from center to center of the ribs.

Reinforced concrete columns shall be proportioned on the assumption that the concrete and the steel are shortened in length in the same proportion. The steel members shall be tied together at intervals sufficiently short to prevent buckling.

If a column is loaded eccentrically or transversely, the maximum fiber stress, taking account of the direct compression, the bending which it causes, its eccentricity and the transverse load, shall not exceed the maximum allowable stress in compression.

If a tension piece is loaded eccentrically or transversely, the maximum fiber stress, taking account of the direct tension, its eccentricity and the transverse load, shall not exceed the maximum allowable stress in tension.

An eccentric load upon a column shall be considered to affect eccentricity only the length of column extending to the next point below at which the column is held securely in the direction of the eccentricity.

If a piece is exposed to tension and compression at different times, it shall be proportioned to resist the maximum of each kind, but the unit stresses shall be less than those used for stress of one kind, depending upon the ratio and the relative frequency of the two maxima.

EXTRACT FROM BUILDING LAWS OF CITY OF BUFFALO (1909). CONCRETE CONSTRUCTION.

Concrete may be used in buildings of all classes when such construction is approved by the Deputy Building Commissioner.

Regulations regarding the use of concrete in hollow blocks and in reinforced steel construction:

Height of buildings.—Buildings whose exterior walls are of *hollow concrete blocks* may be erected not to exceed 3 stories in height, and the thickness of such walls shall be as given below for brick walls; provided, however, that the materials of construction are not strained beyond the safe limits:

Stories.	Buildings of Class I: Sale, storage or manufacture of merchandise, and public livery, boarding or sale stables.					Buildings of Classes II, III, IV: all other buildings, as hotels, hospitals, office buildings, halls, theaters, etc.				
	Basement.		Story.			Basement.		Story.		
	Stone.	Brick.	Gro'nd	2	3	Stone.	Brick.	Gro'nd	2	3
1	18"	12"	12"			18"	12"	12"		
2	18"	16"	12"	12"		18"	16"	12"	12"	
3	20"	16"	16"	12"	12"	20"	16"	12"	12"	12"

Buildings whose exterior walls are of reinforced concrete steel may be erected 3 stories in height, and the thickness of such walls shall be as given in the following table; provided, that the materials of construction are not strained beyond the safe limits:

Stories.	Basement.	1st Story.	2nd Story.	3rd Story.
1	8"	6"		
2	10"	6"	6"	
3	12"	8"	6"	6"

Concrete must be mixed in the proportions of 1 of Portland cement, 2 of sand, and 5 of stone or gravel; or the proportions may be such that the resistance of the concrete to crushing shall not be less than 2,000 lbs. per sq. in. after hardening for 28 days, by approved test. The concrete used in reinforced concrete steel construction must be what is usually known as a "wet mixture."

"Reinforced concrete steel" shall be understood to mean an approved concrete mixture reinforced by steel of any shape, so combined that the steel will take up the tensional stresses and assist in the resistance to shear.

Concrete construction will be approved only for buildings which are not required to be fireproof by the building ordinances, unless fire and water tests shall have been made under the supervision and to the satisfaction of the Deputy Building Commissioner. Each company offering a system of concrete construction for fireproof buildings must submit such construction to a fire and water test.

Inspection and tests.—The execution of concrete work shall be confided to workmen who shall be under the control of a competent foreman or superintendent, and persons erecting buildings of concrete shall provide for expert inspection of the cement and inerts and a daily record shall be kept of the tests, the temperature in which the concrete was worked, and all other conditions which may be of importance in the construction, and a certified copy of such record shall be filed twice each week, or oftener if required.

Quality of materials.—Only high grade Portland cement shall be permitted in concrete construction. Such cement when tested, after 1 day in air and 6 days in water, shall develop a tensile strength of at least 500 lbs. per sq. in.; and after 1 day in air and 27 days in water shall develop a tensile strength of at least 600 lbs. per sq. in. Other tests as to fineness, constancy, volume, etc., shall be made in accordance with the standard

method prescribed by the Committee of the Am. Soc. C. E., as may from time to time be directed.

The sand to be used must be clean, sharp grit sand, free from loam or dirt.

The stone used in the concrete must be clean broken stone or gravel, of a size that will pass through a $\frac{1}{4}$ -in. ring. In case it is desired to use other materials or other kinds of stone, samples of same must be submitted for approval.

Reinforced concrete steel must be so designed that the stresses shall not exceed the following limits:

Extreme fiber stress on concrete in compression, 500 lbs. per sq. in.

Shearing stress in concrete, 50 lbs. per sq. in.

Concrete in direct compression, 350 lbs. per sq. in.

Tensile stress in steel, 16,000 lbs. per sq. in.

Shearing stress in steel, 10,000 lbs. per sq. in.

Adhesion of concrete to steel, not greater than shearing strength of concrete.

Modulus of elasticity of concrete to steel, 1 to 12.

Bending moments.—The following assumption shall guide in the determination of the bending moments due to the external forces: Beams and girders shall be considered as simply supported at the ends, no allowance being made for continuous construction over the supports. Floor plates when constructed continuous and when provided with reinforcement at top of plate over the supports, may be treated as continuous beams, the bending moment for uniformly distributed loads being taken at not less than $WL+10$; the bending moment may be taken $WL+20$ in the case of square floor plates which are reinforced in both directions and supported on all sides. The floor plate may be taken as part of the beam or girder in computing its moment of resistance to the extent of not more than 10 times the width of that beam or girder.

Resisting moments.—The moment of resistance of any reinforced concrete steel construction under transverse loads shall be determined by formulas based on the following assumptions:

The bond between concrete and steel is sufficient to make the two materials act together as a homogeneous solid.

The strain in any fiber is directly proportionate to the distance of that fiber from the neutral axis.

The modulus of elasticity of the concrete remains constant within the limits of the working stresses.

The tensile strength of the concrete shall not be considered.

When the shearing stresses developed in any part of the construction exceeds the safe working strength of the concrete, a sufficient amount of steel shall be introduced in such a position that the deficiency in the resistance to shear is overcome.

When the safe limit of adhesion between the concrete and steel is exceeded, some provision must be made for transmitting the strength of the steel to the concrete.

Columns.—Reinforced concrete steel may be used for columns in which the ratio of length to least side or diameter does not exceed 16. The reinforcing rods must be tied together at intervals of not more than the least side or diameter of the column.

Tests.—Tests must show that the construction will sustain a load of 3 times that for which that portion of the building is designed, without any sign of failure.

***Hollow concrete blocks** used for outside walls and partitions shall not be loaded to more than 150 lbs. per sq. in. of available or effective section, and the hollow spaces shall not exceed $\frac{1}{2}$ the area of the blocks when using the tables for thickness of walls.

Untried methods of construction may first require preliminary trial tests.

Frost.—The influence of frost must be excluded when concrete work is one.

* For specifications for hollow concrete building blocks in the city of Philadelphia, see Sec. 25, Masonry, page 450.

Concrete Base for Plank Flooring on Reinforced-Concrete Floor-

News, Nov. 18, 1909).—For second-story floor of factory. Laying the plank flooring directly on sleepers embedded in the concrete slab (ordinary method), in this case (for fear that dry rot would destroy the sleepers and the flooring immediately next to the concrete layer of sand mixed with coal tar was filled between the ground story and its flooring: First, a mixture of 50 gals. of coal-tar (No. 5) to each cu. yd. of sand was spread $1\frac{1}{2}$ ins. thick on the floor while still warm and soft with a straight-edge. Second, on this there was then placed a layer of 2-in. plank, then $\frac{3}{4}$ -in. rough pine flooring, finally a wearing surface of $1\frac{1}{2}$ -in. square edge maple; the difference of planking being placed in different directions, compacting the floor to about 1 in. in thickness. The floor is solid but resilient and relatively noiseless.

Reinforced-Concrete Car Barns; Separately Molded vs. Monolithic (By M. D. Pratt. Eng. News, Dec. 9, 1909).—Illustrations: Details, separately-molded construction. Tables: (1) Cost of separately-molded construction; (2) Comparative cost between separately-molded and cast-in-place construction. Conclusion: Separately-molded is cheaper.

Building Regulations for the Use of Reinforced Concrete (Cement Users, Chicago convention amendment, 1910; Eng. 5, 1910).—Condensed digest:—Walls—9. Rein.-conc. walls, of any thickness called for brick or stone walls, may be used. Curtain walls less than 4 ins. thick. 10. Conc. walls must be reinforced in both directions. Max. spacing of bars to be 18 in. centers, reinforcement in both directions to be considered. Total reinforcement not less than 4% of concrete. 19. Shall not be used for reinforced-concrete structures;

it may be used for fireproofing. **Assumptions in Design.**—43. The span length for beams and slabs shall be the dist. c.-c. of supports, but not to exceed the clear span plus the depth of beam or slab; brackets shall not be considered as reducing the clear span. 44. Length of columns shall be the max. unsupported length. 45. Where slabs and beams are figured as simple beams the length shall be the clear dist. between supports excluding brackets. **Loads.**—47. Weight of rein.-conc. to be taken as 150 lbs. per cu. ft. 49. The roof shall be figured to carry 30 lbs. live load per sq. ft. unless otherwise noted. 50. A reduction of live load coming to the column supporting the floor below the roof of 5% to be allowed and a further reduction of 5% of the live load of each story below until the total reduction shall amount to 50% of the live load of any floor, after which all loads shall be figured net to the foundations. These reductions shall not apply to storage warehouses. 51. No reduction of loads shall be allowed for figuring floor slabs. 52. Nor none for figuring beams. 53. A reduction of 15% live load may be allowed in figuring the girders, except in buildings used for storage purposes. 54. In assuming the load coming to the columns all beams and girders shall be considered as carrying a net load consisting of 100% each of live load, subject to the above reductions. **Bending Moments.**—55. Slabs.—The bending moment of slabs uniformly loaded and supported at two sides only shall be taken as $wl^2/8$, where w =unit load and l =span. 56. Continuous Slabs.—For interior slabs overhanging two or more supports the bending moment shall be taken as $wl^2/12$. The reinforcement at the top of the slab over supports must equal that used at the center. 57. Slabs Reinforced in Both Directions.—Slabs reinforced in both directions and supported on four sides and fully reinforced over the supports (the reinforcement passing into the adjoining slabs) may be figured on the basis of bending moments equivalent to $wl^2/8$ for load in each direction. When span under consideration is not continuous, $F=8$; when continuous over one support, $F=10$; when continuous over both supports, $F=12$. The distribution of the loads to be determined by the formula: $r=L^4/(L^4+b^4)$, in which r =proportion of load carried by the transverse reinforcement, L =span, b =breadth of slab. 58. The slab area may be reduced by one-half as above figured, when the reinforcement is parallel to and not further from the supports than $\frac{1}{4}$ of the shortest side. The reinforcement spanning the shortest direction shall be below the reinforcement spanning the longer direction, and shall not be further apart than $2\frac{1}{2}$ times the thickness of the floor including the finish. 59. Simple Beams.—The bending moment of beams supported at the ends only shall be figured as of simple beams. 60. Partially Restrained Beams.—Beams supported at one end and continuous at the other to be figured partially restrained with a bending moment of $\frac{1}{8}$ that of a simple beam. When the over-all vertical distance of the tension members is greater than $\frac{1}{4}$ of the total depth of the beam the stresses in each member shall be computed in proportion to the distance from the neutral axis. Beams supporting rectangular slabs reinforced in both directions shall be assumed to take the following load: The beams on which the shortest sides of the slab rest shall take the load of that portion of the slab formed by the isosceles triangle having this side as its base and half this side as its height. The load from the remaining portion of the slab shall go to the beams on which the long side of the slab rests. 62. Continuous Beams.—When beams or girders are continuous over two or more supports, the interior beams may be considered as partially restrained, and the bending moments at the center and support figured as $\frac{1}{8}$ that of a simple beam, unless the concrete at the bottom of the beam at the support shall by this consideration receive excess compression. 63. T-Beams.—In beam and slab construction, an effective metallic bond should be provided at the junction of the beam and slab. When the principal slab reinforcement is parallel to the girder, transverse reinforcement shall be used extending over the girder and well into the slab. 64.—Where adequate bond between slab and web of beam is provided, the slab may be considered as an integral part of the beam, but its effective width shall not exceed $\frac{1}{4}$ on either side of the beam, nor be greater than 6 times the thickness of the slab on either side of the beam. Measurement from the edge of the web. 65. In the design of T-beams acting as continuous beams, due continuation should be given to the compressive stresses at the supports at the bottom of the beam. **Ratio of Moduli.**—75. The ratio of moduli of elasticity of concrete to steel shall be considered as 1 to 15. 76. The allowable tensile stress in reinforcement to be 16,000 lbs. per sq. in. for medium steel and 20,000 lbs. per sq. in. for high elastic limit steel with adequate mechanical bond. 77. The compres-

steel reinforcement to be 15 times the allowed compression which the steel is embedded. **Fireproofing.**—78. For main columns, 2 ins. of concrete; girders, 1½ ins.; floor slabs,

Formulas for Statically Indeterminate Members and Frames (By Eng. News, May 26, 1910).—Formulas and illustrations. (a) Eccentrically-loaded column; base fixed, top hinged. (b) Frame-and-roof column. (c) Frame of two columns and capital. (d) General case of two-story framed bent. (e) Kneebraced bent.

Steel Details in the Ball Realty Building, New York (Eng. News, May 26, 1910).—Details of foundation cantilever, designed to obviate the need of making large excavations and underpinning an adjacent building. Details of pier shelves, suspended wall beam, depressed wall channel.

Structural Steelwork with the Oxy-Acetylene Flame, in Dissolving (Eng. Rec., Aug. 27, 1910).—The acetylene flame was used to cut 12 columns, four 12-in. I-beams, eight 20-in. I-beams, 2 in. deep, and for cutting holes in 8 underpinning piles and in them in two in the middle; the piles were regular 16-in. steel pipe in concrete and about 70 ft. long. The average speed of cutting with the flame is one 24 x ½-in. plate in 1 min., but on heavy solid steel it was great as a 4½ x 4½-in. section in 1 min. has been attained. Done with a portable plant including three acetylene safety lamps, those used for car lighting apparatus and other purposes. The gas was 12 ins. in diameter, and 26 ins. long and contained 225 cu. ft. of gas at atmospheric pressure, compressed to a pressure of 100 lb. per sq. in.

Design of Mill Buildings (By Albert Smith. Paper before Western Assn. Nov. 9, 1910; Eng. News, Nov. 24, 1910).—Mr. Smith advocating the wind loads equally on the two walls, and inward on the windward and leeward roofs respectively, as giving less stress in members of the roof-truss, as giving less deflection of e-braces and columns, and as permitting the rational design of the roof. (1) An accurate determination of the point of contraflexure in the columns. (2) Making the amount of the wind-pressure for the roof a matter to be decided in the light of the exposure of that

48.—RETAINING WALLS.

The forces acting on a retaining wall, due to the pressure of the earth behind it, are not susceptible of exact determination. Several theories have been advanced from time to time, based on assumptions more or less at variance with practical conditions, and from these theories formulas have been deduced, but they are not relied upon with any degree of certainty. We depend rather upon the proportions of existing structures for our designs. Some data have been obtained from tests of models, but the conditions under which the tests were made are not considered sufficiently reliable upon which to base a general working formula.

Theory of Earth Pressure (No. 1).—Any theory of earth pressure should be founded on assumptions clearly and carefully made, and leaning rather on the side of safety than otherwise. It is believed that in the present discussion a clearer conception may be had by taking a concrete example for an illustration.

The diagram shows a horizontal line labeled "Top of F.N." with points 'a', 'b', and 'c' marked. Point 'c' is on the left, 'a' is in the middle, and 'b' is on the right. A vertical line segment is drawn below the horizontal line, starting from point 'a' and extending downwards. There are also small vertical tick marks on the horizontal line between 'a' and 'b'.

Let us consider an earth fill 20 ft. high, level, and of indefinite extent. Imagine this fill to be cut by the vertical plane ab ; then will there be on either side of the plane a set of equal and symmetrical forces acting on the plane, in equilibrium. What is the nature of these forces, their intensities and directions, and their resultants?

Fig. 1.

Firstly, it is assumed that the earth fill is dry and granular, in fact sand, as that will probably produce about the greatest pressure*; also that there is no cohesion among the grains of sand and hence there can be no tension in any part of the mass. If now the fill to the right of the plane ab is removed, it is clearly evident that certain forces as p , whose resultant is P , may be applied on the right face of the plane to hold the fill to the left of it in place, and maintain equilibrium as before. In Fig. 1 these forces are represented as acting horizontally, but no assumption is being made at present as to the direction of the *original* forces on the plane ab due to the earth fill removed, nor to the direction of the *existing* forces acting to the *left* of the plane due to the earth fill in place. It is assumed merely that the p forces represent in intensity the horizontal components of these forces, in the direction of the former and opposite in direction to the latter.

Let us next remove the plane ab , the forces acting to the right of it, and also that portion of the ground line to the right of a , if we can so stretch our imagination. Immediately, the sand will begin to slide over fan-like planes radiating from a : There will be a tendency for the whole triangular prism abd to slide *en masse* on some plane ad , and the general movement of the earth will not cease until some plane ac is exposed and all the material above is removed. It will further be found that this plane ac makes an angle $\phi = 33^{\circ}41'$ (about) with the horizontal. This angle is called the *angle of repose*, angle of friction,[†] or natural slope for that material. It is based on the engineer's slope of $1\frac{1}{2}$ horizontal to 1 vertical, which earth fill in general assumes, and is the slope at which the material will just barely remain at rest. For instance, if we consider the mass of earth abc restored above the plane ac and assume it for the moment to have sufficient cohesion so that no sliding plane *above* the plane ac can develop through it, that is, no part of the mass abc can slide on the other part, then will the mass be at rest, as the tendency to slide on the plane ac will just equal the resistance due to friction. Clearly, then, considering the prism abc as a *united mass*, it is evident from the foregoing that no *horizontal* pressure would be exerted

* The exception to this is clean, coarse, uncemented gravel; see page 838.

† The coefficient of friction = $\tan \phi$.

by it, and hence no forces p , acting on the face ab , would be needed to keep it in place. As such it would exert a vertical force $=W$, a normal force $W \cos \phi = W$, and a tangential force on the plane ac equal to $W \sin \phi = W$, $=W$, $\tan \phi = (W \times 1) \div \frac{1}{2} = \frac{1}{2} W$. The tangent of the natural slope, or $\tan \phi$, equal to $\frac{1}{2}$ for earthwork, is commonly termed the *coefficient of friction* because it requires a force a little greater than $\frac{1}{2}$ of the normal pressure on the natural slope, to move the mass. Hence the united prism abc is just stationary on the $\frac{1}{2}$ to 1 slope ac , because the total friction, $\frac{1}{2} W = W$, the tangential force (1)

Slope of Maximum Pressure.—Consider any triangular prism abd , Fig. 1, resting on the sliding plane ad whose base is x , height h , and length perpendicular to the paper is one—all in feet. The weight of the material composing the fill is taken at 100 lbs. per cu. ft. Then, with the center of gravity at B , we have:

$$\text{Vertical force or weight, } W = \frac{100hx}{2} \text{ lbs.};$$

$$\text{Normal force (to plane } ad), W_n = W \cos \alpha = \frac{100hx}{2} \cdot \frac{x}{\sqrt{h^2 + x^2}};$$

$$\text{Tangential force (on plane } ad), W_t = W \sin \alpha = \frac{100hx}{2} \cdot \frac{h}{\sqrt{h^2 + x^2}};$$

$$\text{Total friction (on plane } ad), f = \frac{1}{2} W_n = \frac{100hx}{3} \cdot \frac{x}{\sqrt{h^2 + x^2}};$$

and the resultant force R , parallel with the sliding plane ad , will equal the tangential force minus the total friction, or

$$R = \frac{100hx}{2} \cdot \frac{h}{\sqrt{h^2 + x^2}} - \frac{100hx}{3} \cdot \frac{x}{\sqrt{h^2 + x^2}} \dots \dots \dots (2)$$

By placing the first differential coefficient equal to zero, and solving for maximum,

$$\frac{dR}{dx} = \frac{(h^2 + x^2)^{\frac{1}{2}} (50h^2 - 66\frac{2}{3}hx) - (50h^2x - 33\frac{1}{3}hx^2)x(h^2 + x^2)^{-\frac{1}{2}}}{h^2 + x^2} = 0$$

$$\text{whence, } (h^2 + x^2) (50h^2 - 66\frac{2}{3}hx) = 50h^2x^2 - 33\frac{1}{3}hx^3.$$

$$\text{or, } x^3 + 2h^2x = \frac{3h^3}{2} \text{ (General equation.)} \dots \dots \dots (3)$$

Solving this cubic equation there is obtained

$$x = .627 h; \text{ whence } \alpha = 57^\circ - 55'.$$

Hence, the *maximum pressure in a direction parallel with the slope*, against the vertical plane ab , obtains when we consider that the sliding plane makes an angle $\alpha = 57^\circ - 55'$ with the horizontal; and when $h = 20$, $x = 12.54$. Substituting the value of x in equation (2), or the values of α and x in the following:

$$R = 50hx \sin \alpha - 33\frac{1}{3}hx \cos \alpha \dots \dots \dots (4)$$

we have, $R = 12540 \times .847 - 8360 \times .531 = 6182$ lbs. Hence, from the above analysis, the resultant pressure R , due to the earth sliding on the plane of maximum slope pressure, is 6182 lbs., which force is assumed to act parallel with the direction of the sliding plane, through the center of gravity B of the mass, and intersecting the vertical plane ab at a point distant $\frac{1}{2}h$ below the top of fill (Fig. 1).

In a similar manner the total horizontal pressure $H (=R \cos \alpha)$, against the wall, may be found; thus,

$$H = R \cos \alpha = \frac{50h^2x^2 - 33\frac{1}{3}hx^3}{h^2 + x^2} \dots \dots \dots (5)$$

Placing the first differential coefficient $\frac{dH}{dx}$ equal to 0 and solving, we have, $x^3 + 3h^2x = 3h^3$, and for maximum value of H we have $x = 0.8178 h = 16.36$ ft.; whence $\alpha = 50^\circ - 43'$, and $H = 16360$ ($\sin \alpha = \frac{1}{2} \cos \alpha$) $\cos \alpha = 3645$ lbs., applied horizontally at c , Fig. 1. Neglecting friction on slope, $H = 8016$ lbs., making the lateral pressure about 40% of the vertical pressure, which may be considered a maximum for any earthy material.

Assumptions Regarding Friction.—Reverting to Fig. 1, there are two planes where friction may be considered, namely, ad and ab . We have found (equation 4) that the possible friction on the plane ad is $33\frac{1}{2} h x \cos \alpha = 4439$ lbs., which, deducted from the tangential force, $50 h x \sin \alpha$ (or 10621 lbs.), gives 6182 lbs., the resultant. Hence, if the friction is neglected our resultant will be increased from 6182 to 10621 lbs., an increase of nearly 72%. Should this friction, for safety, be wholly or partly neglected? Before arriving at any conclusion in regard to this, let us consider the possible friction on plane ab . If $a b$ represents the back of the retaining wall, the amount of possible friction will depend upon the construction of the wall itself.

Let Fig. 2 represent a simple frame construction to better analyze the acting forces. The resultant force R is resisted by the strut $c e$, and hence the stress in the latter is equal and opposite to R . The point c is the center of gravity of the distributed earth pressure acting on the facing, which is supported by the stud ab , which facing is stiff enough to resist bending, and which is balanced on the pivot or point of support c . As long as the resultant pressure acts parallel to the plane $a d$, as indicated, there will be, apparently, unstable equilibrium; but should it make a less angle than α with the horizontal, then there would be a tendency for the strut $c e$ to revolve about e . In doing so it would tend to raise the facing $a b$, thereby causing friction of the latter against the earth fill. Indeed, as the forces now act, the resultant R can be transmitted to the strut $c e$ only on the assumption that there is sufficient frictional force downward on the "fill" face of the wall to resist the vertical component of the stress in the strut $c e$. Let us examine this: Assuming the coefficient of friction of the earth on the face of the wall as equal to $\frac{1}{2}$ of the normal pressure, there is obtained,

Total friction = $\frac{1}{2} R \cos \alpha$
 = 2189 lbs. for $R = 6182$;
 = 3760 lbs. for $R = 10621$.

This friction on the "fill" face of the wall will be opposed by the vertical component of the stress in the strut $c e$, equal to

$R \sin \alpha$
 = 5236 lbs. for $R = 6182$;
 = 8996 lbs. for $R = 10621$.

Hence it is evident that the wall may have to be anchored, at a , an amount equal to

Vertical component of R —(total friction + wt. of wall)
 of else the strut $c e$ will have to have a less inclination with the horizontal.

Similarly, the preceding form of analysis may be repeated, but using the maximum value of H obtained from equation (5) with the angle of slope $50^\circ-43'$.

Practical Deductions.—The uncertainty of some of the foregoing assumptions makes the problem a difficult one to solve. However, we are reasonably certain that the resultant pressure on the wall parallel with the sliding plane ad (Fig. 1) is somewhere between 6182 and 10621 lbs. Assuming the latter as correct by neglecting friction on the slope (which can obtain only when the wall begins to tip) we have that the resultant normal pressure P acting horizontally at c is

$$P = R \cos \alpha = 10621 \times .531 = 5640 \text{ lbs.}$$

which is equivalent to a horizontal pressure per square foot on the vertical wall $a b$, varying uniformly from zero at b , to 564 lbs. at a . This is equivalent to stating that the horizontal pressure per square foot against the retaining wall at any point below the top is equal to 28.2 per cent. of the weight of a vertical column of earth, one square foot in section, extending from the top of the fill to that point; that is, the lateral pressure is 28.2 per cent. of the vertical pressure.

For Temporary Shoring, this may be reduced to 25 per cent., or even less, provided of course that the "earth" is not saturated with water so as to be in a muddy condition. Up to a certain point of wetness, moist earth will produce less percentage of lateral pressure than dry, granular earth.

For Permanent Structures, the lateral pressure should be assumed at about 30 per cent. of the vertical, and even up to 33.5 per cent. in places subject to considerable jarring, as for retaining walls supporting railway

Fig. 2.

embankments. Where the weight of a train or of a structure falls within the range of the slope, it can be reduced to an equivalent volume of earth.

If the material is coarse gravel, the ratio of lateral to vertical pressure may reach as high as 40 per cent., for which provision should be made.

Graphical Solution of Preceding Problem.—Fig. 3 is a graphical solution for a masonry retaining wall 20 ft. high to restrain a level earth fill of the same height—the problem which has engaged our attention throughout the discussion of the theory of earth pressure. The weight of the earth fill is assumed at 100 lbs. per cu. ft., and the lateral pressure, 30 per cent. of the vertical. Hence the resultant lateral pressure $P = \frac{30 \times 20^2}{2} = 6000$ lbs., acting

horizontally at a point one-third the height from the bottom. Selecting the trapezoidal type of wall, the center of gravity is found by assuming the top and bottom widths; laying off the bottom width on either side of the top, and the top width on either side of the bottom; and finding the point of intersection of the diagonal lines joining the outer points. The weight of one foot section of wall at 150 lbs. per cu. ft. = 16500 lbs., acting vertically through the center of gravity. From the intersection of the two acting forces the triangle of forces is drawn showing the resultant to intersect the base within the middle third, which is good practice.

Fig. 4 shows another design for the same in which the top width of wall is one ft. instead of three. In this case the resultant falls outside the middle third, and hence there is tension on the face *ab*. In addition to this tension, the factor against overturning at *t* is lessened, and it is not as desirable a type as that shown in Fig. 3.

Top of Fill, Sloping.—Up to the present, we have considered the top of fill level, and flush with the top of the wall. We will now consider what modification of pressure will be effected in case the surface of the fill should slope either upward or downward from the back or, in fact, show any profile whatever. Fig. 5, in which *ab* is the "fill" face of the retaining wall, shows the slopes of maximum pressure for: (1) a level fill *bd*, with maximum pressure slope *ad* making an angle of $57^\circ-55'$ with the horizontal; (2) an upward surface slope *bu*, with maximum pressure slope *au* slightly less than *ad*; and (3) a downward surface slope *bl*, with maximum pressure slope *al* slightly greater than *ad*. It is to be noted that the slopes of maximum pressure *au* and *al* very nearly coincide with *ad*, the slope of maximum pressure which we found for a level fill, and it might also be stated here that this slope, *ad*, may be varied either way several degrees without materially affecting the resultant pressure. Also, as *bu* and *bl* are the upper and lower limits at which earth fill will stand ($1\frac{1}{2}$ to 1), then all other possible surface slopes must be less than these, and in approaching a level their slopes of maximum pressure *au* and *al* will approach *ad* in direction. For all practical purposes *a d* may be assumed as the slope of maximum pressure for any surface slope. This assumption, containing a small percentage of error, greatly simplifies the method of calculation for general cases. For depressed surface slopes, as *bl*, the assumption is on the side of safety; while for surcharged walls with upward slopes, as *bu*, the assumption involves a slightly opposite effect, to counteract which it would be well to have the resultant of all the forces (earth and wall) cut the base of the retaining wall at least $\frac{1}{3}$ of the width from the toe instead of the customary $\frac{1}{3}$.

General Cases.—By observing the following methods a retaining wall may be designed for any surface slope: (1) Draw the back of the wall, *ab* (Figs. 6, 7, and 8); the slope of greatest pressure, *au* or *al*, making an angle

Fig. 3.

Fig. 4.

Fig. 5.

the horizontal ($\tan 57^{\circ}55' = 1.595$, $\cot = 0.627$); and the bu or bl . (2) Find the area and the center of gravity of the abu or abl , above the slope of greatest pressure, au or al . Area by the weight of the fill per cubic foot (average 100 lbs.). (3) Of one lineal foot of fill is laid off to scale of lbs. vertically from the center of gravity $c.g.$ of the mass. The resultant pressure T , parallel with the slope of maximum pressure, au or al , and the resultant pressure P , normal to the face of the wall, ab . (For a vertical wall, $F \sin \alpha \sin \beta = F \sin \alpha \cos \alpha =$ Figs. 6 and 8 show the graphical solution for P , in intensity, point of application, at c . (3) Find the point of application of gravity of the total lateral earth pressure P on the point, c , is at the intersection of the back of the wall (or slope) with a line drawn through the center of gravity, $c.g.$, of the fill, parallel with the slope of maximum pressure, au or al . of P is normal to the back of the wall ab . (4) Assume the wall, as trapezoidal or rectangular, with a base about 70 and find its area and center of gravity. Multiply this area of the masonry per cubic foot (average 150 lbs. for good masonry). This weight W , of one lineal foot of wall is laid off to scale vertically downward from a point o at the intersection of a vertical line through the center of gravity of the masonry, and the force P . W and P are laid off in sequence and the resultant R is drawn. If the base of the wall within the middle third the design is sufficiently safe against overturning, with a proper factor of safety. If the wall is overcharged, as in Figs. 6 and 7, it is better to have the resultant of the base from the toe instead of $\frac{1}{3}$. (5) One or two trials may be necessary before the desired result is attained. (6) Remarks under "Practical Deductions," page 837. The fore-pressure is equivalent to a lateral pressure equal to $28\frac{3}{10}$ per cent. of the vertical for average conditions. If greater or less security is desired, increased or diminished proportionately, depending upon the nature of the structure and the quality of the material composing the base of P of say 20 to 40 per cent. would provide for a permanent supporting a gravel fill or a fill liable to become quite soft with water. For a temporary wall or shoring, P may in some cases be increased from 5 to 10 per cent. This increase or decrease in P is due to the dimensioning of the wall so that, in any case, the resultant falls within the middle third. (7) If any superimposed load, d , comes on the fill, it should be reduced to an equivalent weight of earth, and may be considered as such in finding the weight of center of gravity, $c.g.$

Fig. 7.

Fig. 8.

Theory of Earth Pressure (No. 2).—This theory also assumes material to be granular and without power of cohesion, therefore compressive throughout the mass.

ees with the deduction, page 837, that the lateral pressure for low the surface of a level fill is $28\frac{3}{10}$ per cent. of the vertical though it is not apparent at first glance.

NOTATION.

- w = weight of earth in lbs. per cu. ft.;
 x = vert. depth in ft. below surface, of any (conjugate) plane parallel with the surface plane (Fig. 9);
 θ = angle of inclination of conjugate plane with the horizontal;
 ϕ = angle of repose of earth,* or angle of greatest obliquity;
 p_v = intensity of vert. pres. in lbs. per sq. ft. on any conjugate plane at depth x below surface;
 p_r = intensity of pres. in lbs. per sq. ft., in a direction parallel with the conjugate plane, against a vertical plane (as a retaining wall) at depth x below surface.

FORMULAS.

(Surface plane assumed to be of indefinite extent.)

In general, $p_v = w x \cos \theta$ (1)
 and p_r may have any value between

Fig. 9.

$$p_r \nabla w x \cos \theta \frac{\cos \theta - \sqrt{\cos^2 \theta - \cos^2 \phi}}{\cos \theta + \sqrt{\cos^2 \theta - \cos^2 \phi}} \dots \dots \dots (2a)$$

and $p_r \nabla w x \cos \theta \frac{\cos \theta + \sqrt{\cos^2 \theta - \cos^2 \phi}}{\cos \theta - \sqrt{\cos^2 \theta - \cos^2 \phi}} \dots \dots \dots (2b)$

If h is the height of the retaining wall, the maximum intensity of pressure at the bottom, may be found by substituting h for x in the preceding equations; and as the intensity of pressure at the top of the wall is zero, the average will be one-half the maximum. Hence the total pressure on the wall will equal the average intensity multiplied by the height h , and this to be applied at a point $\frac{1}{3}h$ from top or surface, and in a direction parallel with the conjugate plane.

If the surface plane is horizontal:

Equation (1) reduces to $p_v = w x$ (3)

" (2a) " " $p_r \nabla w x \frac{1 - \sin \phi}{1 + \sin \phi}$ (4a)

" (2b) " " $p_r \nabla w x \frac{1 + \sin \phi}{1 - \sin \phi}$ (4b)

If the surface plane is inclined at the angle of repose so that $\theta = \phi$, then

$$p_v = w x \cos \theta = w x \cos \phi \dots \dots \dots (5)$$

For water, the angle of repose $\phi = 0$, and equations (4a) and (4b) reduce to the hydraulic equation

$$p_r = w x \dots \dots \dots (6)$$

* Usually assumed at $33^\circ 41'$ for earth fill, equal to slope of $1\frac{1}{2}$ to 1, making coefficient of friction ($= \tan \phi$) = $\frac{1}{2}$.

49.—DAMS.

Common Fixed Types.—A dam is a structure designed to hold back a large body of water in an impounding reservoir, at a higher level than would naturally obtain. It should first of all be safe, and the site should be selected with due regard to present and future needs for storage, economy of construction, efficiency of head, outlet, wasteway, etc. With respect to their structural features, dams may be classified as follows:

A *Gravity* dam is a masonry dam designed to resist overturning by the action of gravity alone. It must also resist any tendency to slide horizontally (down-stream) on its base or on any plane above (or below) the base; there must be no tension in the masonry at any point as in the up-stream face where it is most likely to occur; and the compression in any part as the down-stream face, where it is maximum, must not exceed the safe, allowable intensity per square inch.

An *Arched* dam is a horizontally curved (arched) type with ends rigidly braced against the side walls of the canyon—a typical site for this class of dam. The arch is designed to relieve partly—not wholly—gravity requirements although many engineers use the full gravity section that would be required for a straight dam, thereby employing the arch to give greater stability, or in other words, to increase the factor of safety. Although the stresses in an arched dam cannot be determined with accuracy, especially as it acts partly as a gravity dam, being “fixedly” supported throughout its whole length, we know that the arch effect relieves the tendency to overturning, caused by the action of the water pressure on the up-stream face, and this being true, it is evident that the base of the dam can be narrowed materially. This possible reduction of section, however, diminishes as we approach the top of the dam where the combined gravity-, arch- and temperature stresses bear in increased ratio to the gravity stresses alone. Indeed, it has been claimed that, under certain conditions, the arched dam requires a greater section near the top than does the gravity dam, although the writer has never met with such conditions in practice.

A *Buttressed* dam is a gravity dam with buttresses, or thickened sections, spaced at stated intervals for the more economical distribution of the material than one of uniform cross-section. It may be built of concrete, steel-concrete, or stone masonry. The sections at the buttresses will be larger, and the sections between the buttresses will be smaller, than that of an equally safe gravity dam of uniform cross-section. Care should be taken in both the design and construction to avoid any possibility of tension, undue shearing, or excessive compression in any part of the masonry. The facing between the buttresses may be supported by horizontal reinforced concrete beams as used in building construction, or by concrete or stone masonry arches. The facing should practicably be impervious to water.

A *Braced* dam is a dam with braced vertical or sloping face. It differs from a buttressed dam in that the solid masonry buttresses are replaced by open bracing of reinforced concrete, steel or wood. The facing may be of the same character of material, but not connected with the braced legs in such a manner as to form a series of arches between them. A good angle for the face of a braced dam is a slope of 45 degrees with the horizontal, in which case the cost of facing will generally about equal the cost of bracing. But if the facing is very expensive and the bracing cheap, this angle should be increased. The cost of repairs for each should also be considered in determining the economic angle.

A *Cantilever* dam is designed on the cantilever principle and may be braced or buttressed. The facing is supported by beams or trusses projecting beyond the upper limit of the bracing. It may be framed of steel and concrete, reinforced concrete, steel or wood, or a combination of these materials. It should be secured firmly to a natural bed-rock or to a concrete anchorage.

A *Crib* dam is a skeleton, box-like structure weighted with filling and usually faced to prevent undue leakage. The skeleton structure may be composed of logs or of hewn or sawed timbers, framed and bolted into a crib,

filled with rock, slag, gravel or other suitable material, sunk to the bottom (which has been previously prepared) and preferably bolted thereto. Planking makes a cheap facing.

A *Composite* dam is one composed of two or more radically different kinds of material, composite but not structural in character. A good example of a composite dam is the common brush and rock dam, the brush to prevent excessive leakage and the rock to give stability.

A *Filled* dam is one not strictly structural in character, containing little or no cohesion and hence not capable of being "overturned," but which, if flooded (overtopped) with water, will disintegrate and wash away. It may be composed of any durable material of specific gravity greater than unity, as clay, earth, sand, gravel or loose rock. If it is of the finer materials it is called an Earth dam; if of the coarser (rock), a Rock-fill dam.

(a) An Earth dam should be composed of material or materials which will pack well and allow but small voids, if any, and which, under the action of water, will not wash, leaving large holes or pockets. "Cement" gravel is probably the best material as it contains the proper natural binder for a solid mass. If materials are mixed, such as earth, sand, clay, etc., they are better if mixed thoroughly and uniformly—if not, there are liable to be seams of strata allowing the water to percolate and wash the materials. The ratio of 3 horizontal to 1 vertical for the wet slope and 2 to 1 for the dry slope is ordinarily good practice and generally should not be exceeded.

(b) A Rock-fill dam is composed of loose rock dumped—not carefully laid—in place, with proper up-stream and down-stream slopes. The up-stream slope may sometimes be as steep as $\frac{1}{2}$ horizontal to 1 vertical if the rock facing is laid by hand, otherwise 1 to 1 is the usual practice. The dry- or down-stream slope is usually broken, being steeper, say 1 to 1, for the upper and $1\frac{1}{2}$ to 1 or $1\frac{1}{2}$ to 1 for the lower section. The facing may be of double planking, caulked and asphalted, and nailed to wooden stringers, say 6"x6", imbedded in the face rock. The thickness of the planking will of course be greater for the greater head of water.

STABILITY OF GRAVITY DAMS.

A gravity dam to be safe must be built on the natural, hard bed-rock not liable to disintegrate, and capable of withstanding the maximum intensity of pressure at the toe of the dam, to resist overturning. The outlet, for drawing off the water for domestic or commercial uses, is usually by (cast iron) pipes extending through the masonry wall of the dam itself, but preferably by tunnel construction through the solid rock at one side of and apart from the dam. Likewise, the *wasteway*, for carrying off the flood waters, should preferably be at some other point than at the dam itself. In many cases, however, there is no alternative but to let the surplus or waste water from the full reservoir flow over the entire crest of the dam, or through a specially provided wasteway in a certain limited part of the crest.

When the dam acts as a waste-weir, i.e., with the water flowing over the crest, additional forces must be considered as tending to overturn the structure. There are (1) the additional head of water h_1 above the top of the dam; (2) the tension or suction at the rear face of the dam, due to a partial vacuum at *a*, Fig. 1, caused by the falling water taking up the particles of air between it and the rear face of the dam; and (3) the pressure of ice and logs against the upper face. The vacuum effect may be lessened materially by rounding off the rear upper corner of the dam, as shown in Fig. 2.

Fig. 1.

Fig. 2.

Hydrostatic Pressure.—In the discussion of dams and the forces acting against them it is convenient to assume a section of the dam and of the column of water, etc. acting, as one foot thick. The weight of a cubic foot of water is generally assumed at 62.5 lbs., involving an error of $\frac{1}{4}$ of one per cent. on the side of safety. Therefore, the pressure of one square foot of surface at a depth of h feet below the surface is $62.5 h$. It will thus be seen that the intensity of pressure increases uniformly with the depth, and furthermore it is always normal (at right angle) to the surface acted

upon, because, being a frictionless liquid, the pressure is equal in all directions. To find the total pressure, then, on any plane surface one foot wide, whether inclined or not, it is necessary only to find the intensity of pressure per square foot at its "middle point" and multiply this result by the length of the plane. Moreover, as will be shown in the next article, under "Center of Pressure," the total pressure, instead of being assumed as a distributed force, may be assumed to act at the center of pressure, i.e., at the center of gravity of pressure on any "rigid" surface, thereby greatly simplifying the calculations.

The following are common examples of total pressure, the heavy line in each figure representing the edge of the plane, *one foot wide*, acted upon: (H and h are in feet; pressure is in lbs. against the plane ab).

Fig. 3.

Fig. 4.

Fig. 5.

- (1). Vertical plane ab , just touching surface of water. (Fig. 3.)

$$\text{Total pressure} = \frac{62.5H}{2} \cdot H = \frac{62.5H^2}{2} \text{ lbs.}$$

If the surface of the plane makes an angle θ with the vertical, multiply the above result by secant θ .

- (2). Vertical plane ab , submerged below the surface. (Fig. 4.)

$$\text{Total pressure} = 62.5 \left(\frac{H+h}{2} \right) (H-h) = 62.5 \left(\frac{H^2-h^2}{2} \right) \text{ lbs.}$$

- (3). Inclined plane ab , submerged below the surface. (Fig. 5.)

$$\text{Total pressure} = 62.5 \left(\frac{H^2-h^2}{2} \right) \sec \theta \text{ lbs.}$$

This pressure will not be horizontal, but normal to the plane ab ; example (2) illustrates the horizontal component of this pressure.

The above formulas will be found useful in calculating the total pressure on any section of a dam, whether the face is vertical or sloping. The point of application of the resultant pressure will now be discussed.

Center of Pressure.—If the total pressure against any surface as ab , in the preceding illustrations, is concentrated as a single resultant force, this force will act at the *center of pressure*, and *through* the center of gravity of the distributed force. In *Example 1*, above, the resultant P of the distributed force is $\frac{62.5H^2}{2}$ lbs., acting horizontally through the center of

gravity *c.g.* of the pressure triangle abc , at a point p on the face of the dam, distant $\frac{1}{3}H$ below the water surface (Fig. 15). Thus, p is the center of pressure, for the head H , on the plane ab , whether vertical or inclined. Likewise, in *Example 2*, the resultant pressure on the plane ab is $P = \frac{62.5}{2}(H^2-h^2)$ lbs., and the center of pressure, p , is $\frac{1}{3}\left(H + \frac{h^2}{H+h}\right)$ feet below the water surface (Fig.

16). In *Example 3*, the same value, $\frac{1}{3}\left(H + \frac{h^2}{H+h}\right)$, holds true for the distance to the center of pressure below the surface, while the total pressure is of course greater—or

$\frac{62.5}{2}(H^2-h^2)$ times sec angle of inclination with the vertical. For reference, these values are tabulated as follows:—

Fig. 6.

Fig. 7.

HYDROSTATIC PRESSURES ON VERTICAL AND INCLINED SURFACES.

Figure	Angle of Plane with Vertical.	Surface of Water Above Top of Plane. h	Surface of Water Above Bottom of Plane. H	Resultant Pressure on Plane 1-Ft. Wide. P	Distance Center of Pressure Below Surface of Water.
1.....		Ft. 0	Ft. H	Lbs. $31.25 H^2$	Ft. $\frac{H}{3}$
1.....	θ	0	H	$31.25 H^2 \sec \theta$	$\frac{H}{3}$
2.....		h	H	$31.25 (H^2 - h^2)$	$\frac{3}{8} \left(H + \frac{h^2}{H+h} \right)$
2.....	θ	h	H	$31.25 (H^2 - h^2) \sec \theta$	$\frac{3}{8} \left(H + \frac{h^2}{H+h} \right)$

Center of Gravity of Trapezoid.—

Required to find the center of gravity of the trapezoid whose top is T and bottom is B (Fig. 8). Lay off b and t and $t' = T$. The diagonals intersect at o , the center of gravity. The line o bisects T and B . Area $D = \frac{D}{2} \left(\frac{B-T}{B+T} \right)$. In calculation

Fig. 8.

of water pressure is frequently divided into trapezoidal vertical forces of the masonry being the weight of each trapezoid through its center of gravity. The area of the trapezoid =

the weight of a vertical section of masonry one foot thick,

and the pressure due to the corresponding pressure trapezoid, are:

Weight, $W = mD \frac{T+B}{2}$; when m = wt. of one cubic foot of masonry.

Pressure, $P = wD \frac{T+B}{2}$; when w = wt. of one cubic foot of water.

Pressure, $P_n = wD \frac{T+B}{2} \sec \theta$; when w = wt. of one cu. ft. of water.

Illustrated in Fig. 9.

Fig. 9.

Angular Dam.—The simplest form of dam is the triangular dam, Fig. 10. Let ac be any assumed base distant h below the water surface. If w is the weight per

cubic foot of water and m is the weight per cubic foot of masonry, we have, from the preceding:

The resultant horizontal pressure, $P = \frac{w H^2}{2}$.

The total weight of masonry, $W = \frac{m b h}{2}$.

Now, if it is desired that the resultant, R , shall intersect the base, b , at the edge of the "middle third," as shown in Fig. 10, we have that

$$\frac{P}{W} = \frac{b}{3} + \frac{H}{3} = \frac{b}{H}, \text{ whence by substitution,}$$

$$\frac{w H^2}{2} + \frac{m b h}{2} = \frac{b}{H}; \text{ or } b = \sqrt{\frac{w H^3}{m h}} \dots \dots \dots (1)$$

If $H = h$, this reduces to $b = h \sqrt{\frac{w}{m}} \dots \dots \dots (2)$

If w (water) = 62.5, and m (masonry) = 146,* $b = 0.654 h \dots \dots \dots (3)$

It is desirable, sometimes, to have the resultant cut the base $\frac{1}{3} b$ (instead of $\frac{1}{2} b$) back from the toe, in which case we will have, $b = 0.7 h \dots \dots \dots (4)$

Fig. 10.

Pressure on Foundations.—If two *stiff* pencil erasers, Fig. 11, are pressed *moderately* together by equal and opposite forces W and W' applied *near* the left end, a , it will be seen that they do not remain in contact throughout their entire length, but separate at the right end, e . Moreover, it will be found that the length of contact to the right of the applied force is double the contact length to the left, and therefore $\frac{1}{3}$ of the total contact b . Similarly, we have in the case of the dam abc , Fig. 10, that when the reservoir is *empty* and consequently there is no water pressure on the face ab , the resultant force is W , the weight of the masonry, acting as shown in Fig. 11. Hence, we may say that for a triangular dam with a vertical face ab the resultant weight when dam is empty will produce a pressure intensity on the base varying uniformly from zero at the lower toe, c , to a maximum ($m h$) at the upper heel, a , Fig. 12. The exact results given above may be deduced by mathematical analysis, which, however, will be omitted here.

Fig. 11.

Fig. 12.

Let us now consider the forces acting on the plane ac , Fig. 10, due to the *water pressure* P . Imagine the dam to be a vertical beam of length $a b$ and "fixed" at the lower end, $a c$. Consider the depth of the beam, b , and the width (vertical with the plane), unity. The acting force, P , is $\frac{w H^2}{2}$, the lever arm is $\frac{H}{3}$, and hence the bending moment about the section $a c$ is $\frac{w H^2}{2} \cdot \frac{H}{3} = \frac{w H^3}{6}$. The resisting moment of the beam at the section $a c$ is $\frac{1}{2} f b^2$. Equating, $f = \frac{w H^3}{b^2}$ = the compressive stress at c and the tensile stress at a , considering the neutral axis midway between. If the reservoir is full of water, $H = h$ therefore $f = \frac{w h^3}{b^2}$ (Fig. 13).

By combining Figs. 12 and 13 we are enabled to obtain the vertical component of the distributed stress on the foundation or on any plane above same. In addition to this there is the horizontal

Fig. 13.

* Specific gravity = $146 \div 62.5 = 2.336$; often assumed at 2.4.

† The resisting moment of a rectangular beam about a neutral axis passing through the center of section is $M_r = \frac{1}{2} f \times \text{breadth of beam} \times (\text{depth of beam})^2$; in which f = outer fiber stress.

shear ($=P$) which may be considered as distributed in intensity varying directly with the vertical pressure at any point. Hence the resultant intensities will be parallel with the resultant R , Fig. 10.

Combining the stress due (1) to the weight of the masonry dam, and (2) to the water pressure on the face $a c$, we have, for the triangular dam,

$$\text{Vertical stress at } a \text{ per sq. ft.} = f_a = \frac{w H^2}{b^2} - m h \dots \dots \dots (5)$$

$$\text{ " " " } c \text{ " " " } = f_c = 0 - \frac{w H^2}{b^2} \dots \dots \dots (6)$$

The result is tension if "plus," compression if "minus."

The following example is solved by equations (5) and (6). Wt. of water, w , is assumed at 62.5; masonry, m , 146 lbs. per cubic foot; see also Fig. 10.

Example.—What is the effect on the resultant pressure, R , Fig. 10, when the reservoir is being filled?

Solution.—(a) When the reservoir is empty we have from equation (5), $f_a = -146 h$, that is, the intensity of compression per sq. ft. at a is equal to $146 \times$ height of dam in feet. If the limiting pressure on masonry is assumed at 30,000 lbs. per sq. ft. it will be seen that the limiting height of

the dam will be, $h = \frac{30\,000}{146} = 205\frac{1}{2}$ feet, when the dam is empty, and that the

pressure on the foundation uniformly decreases from 30,000 lbs. per sq. ft. at a to zero at c (see Fig. 12). (b) If, now, the reservoir is gradually filled, the horizontal pressure P increases with H^2 and the distance to center of pressure above the base increases with $\frac{H}{3}$. The resultant pressure R will

gradually swing to the right from the vertical position W and with increasing magnitude. It will be found also that the intensity of pressure at a will gradually decrease with the corresponding increase of pressure at c , while R is traveling across the middle third of the base. By the use of equations (5) and (6) the intensities of pressure f_a and f_c can readily be obtained by substituting the values of the unknown quantities. (c) Lastly, we will consider the reservoir as full, that is, the water is assumed to be at its flood height. In this case, H may be slightly less than, equal to, or greater than, h . The resultant R , Fig. 10, is now cutting the base at, say, the extreme right edge of the middle third, whence the compression at a is reduced to zero, while the compression at c has reached the maximum. Therefore it is evident from equation (5) that if $f_a = 0$,

$$\frac{w H^2}{b^2} = m h \dots \dots \dots (7)$$

from which, the value of any factor may be found by assuming values for

the other factors. Thus, $b = \sqrt{\frac{w H^2}{m h}}$, which compare with equation (1).

If $H = h$, this reduces to equation (2), or $b = h \sqrt{\frac{w}{m}}$. Assuming water (w)

at 62.5, and masonry (m) at 146, we have, $b = 0.654 h$, equation (3). If now this value of b is substituted in equation (3) and $w = 62.5$, we have, when reservoir is full,

$$f_c = - \frac{62.5 H^2}{(0.654 h)^2} = - \frac{62.5 h^2}{0.4277 h^2} = -146 h, \text{ or}$$

the same result which was obtained for f_a with the reservoir empty. It is to be noted, also, that the most economical type of dam approaches the triangular section with a vertical up-stream face.

General Formulas for Pressure on Foundations.—For any type of gravity dam the following formulas may be applied with a reasonable degree of accuracy, or at least sufficiently so for all practical purposes:

NOTATION.

W = total weight in lbs. of "section-foot" of masonry above plane $a c$.
 b = width of base $a c$ in feet, with center of base at origin, *origle*

- x = distance in feet from origin o , to point of application of the resultant, R , on ac ; $+x$ if down-stream, $-x$ if up-stream, from o .
 f_a = vertical intensity of stress in lbs. per sq. ft. at a .
 f_c = vertical intensity of stress in lbs. per sq. ft. at c .
 β = angle of inclination of resultant R with the vertical.
 F_a = intensity of stress in lbs. per sq. ft., parallel with R , at a .
 F_c = intensity of stress in lbs. per sq. ft. parallel with R , at c .

Fig. 14.

FORMULAS.

$$\begin{aligned}
 f_a &= -\frac{W}{b} \left(1 - \frac{6x}{b}\right) \dots\dots\dots (7) \\
 f_c &= -\frac{W}{b} \left(1 + \frac{6x}{b}\right) \dots\dots\dots (8) \\
 F_a &= -\frac{W}{b} \left(1 - \frac{6x}{b}\right) \sec \beta \dots\dots\dots (9) \\
 F_c &= -\frac{W}{b} \left(1 + \frac{6x}{b}\right) \sec \beta \dots\dots\dots (10)
 \end{aligned}$$

If the result is minus, the stress is compression; if plus, it is tension.

Note that f_a and f_c are vertical components of F_a and F_c ; also that when $+x$ or $-x$ is equal to $\frac{b}{6}$, the resultant pressure cuts the base at the edge of the middle third; whence f_a is respectively equal to 0 or to $-\frac{2W}{b}$, and f_c is respectively equal to $-\frac{2W}{b}$ or to 0. That is to say, that when the resultant cuts the base within the limits of the middle third there will be no tension in any part of the masonry.

Table 2, next page, is based on allowable tension in the masonry, but in actual practice tension is not allowable in the masonry of a gravity dam.

Factor of Safety Against Overturning.—With the resultant pressure R cutting the base at the lower edge of the middle third, Fig. 10, when the reservoir is full and the water pressure P is maximum, it is to be noted that the factor of safety of the dam, against overturning, is 2, because if P is doubled, R will pass through the lower toe at c , whence the dam will be on the point of overturning. The nearer to the center of the middle third that R intersects the base, the greater is the factor of safety. If it intersects in the middle third, the factor is 2 or greater; if in the outer third, the factor is between 1 and 2; if at the outer toe, c , the factor is 1; if outside the outer toe, the factor is less than 1, and hence the dam will overturn. These principles apply not only to the triangular dam but to any practical type.

Shear.—The horizontal shear on any plane ac is equal to the horizontal component of the total water pressure on a section-foot above that plane, or equal to $P \cos \theta$. If W = the total weight of the masonry resting on the joint ac , and f = the coefficient of friction, then $f(W + P \sin \theta)$ = the total resisting force due to friction. Hence, if the joint ac is assumed to be a horizontal plane with no adhesion, but simply friction, between the two surfaces in contact, we have, for equilibrium,

$$P \cos \theta \leq f(W + P \sin \theta) \dots\dots\dots (11)$$

In ordinary practice, f may be assumed at $\frac{1}{3}$, hence $P \cos \theta$ must not exceed $\frac{1}{3}(W + P \sin \theta)$. Equation (11) may be used safely in designing because $f(W + P \sin \theta)$ does not represent the entire resisting force. In fact, horizontal and unbroken joints are avoided in practical construction, and hence considerable shearing resistance is introduced, thereby increasing the factor of safety against sliding, materially.

Plus=tension; minus=compression. See notation, page 849.

Author's Type of Dam.—The author submits Fig. 16 as a type which may be used, ordinarily, up to 200 ft. in height, every part to be enlarged proportionately. The dimensions shown in the figure are based on a height of unity. If the proposed height of dam is 50 ft., multiply each dimension by 50; if 100 ft., multiply by 100; if 200 ft., multiply by 200; etc. In approaching the upper limit of height, care must be used to see that the maximum allowable pressures per square foot on the base and foundations are not exceeded. Table 2, preceding, may be consulted with regard to the pressure on foundations. If for any proposed height, say 225 ft., the pressure on the foundations would be excessive, the type may be proportioned for a height which will not produce excessive pressure, say for 200 ft., and the side lines projected further downward, below the E' level, the necessary distance. Note that the up-stream face below the B' level is a series of chords touching an imaginary parabolic curve at their vertices, while the down-stream face is a straight line; also that above the B' level the up-stream face is vertical and the down-stream face is a parabola. The design is based on the masonry having a specific gravity of $2\frac{1}{2}$, which is equivalent to 145.83 lbs. per cubic foot, hence the engineer is cautioned not to use this type, unmodified, for masonry of less specific gravity.

Calculations of Author's Type of Dam (Fig. 16).—The triangular type of dam, with an apex at b , Fig. 10, is never adopted in practice. The practical type is never allowed to come to a point at the top, but has a certain top width, say about one-tenth the height of the dam, giving mass to resist any forces acting at the surface such as those due to floating ice, logs, etc. This width also provides usually for foot-path and roadway, either expressly or incidentally, and for a general promenade if the dam is high and in a picturesque site. Another departure from the triangular dam is the upstream face $a b$, which is battered more or less instead of being vertical. With these conditions imposed the problem becomes, by comparison, a complicated one when we wish to design a type having practical lines, containing the least amount of masonry, and whose resultant lines of pressure must generally coincide with the edges of the middle third. In Fig. 10, the triangular type, line E represents the line of resultant pressure when the reservoir is empty, and line F when full. They are both straight lines and are drawn from b to the base, cutting the latter in three equal parts. Likewise they will cut any parallel plane above the base in a similar manner, and hence the triangular type is an ideal one, easy to calculate.

There are several methods in use in designing dams. The "cut-and-try" method is the one here presented, and Fig. 16 is the result of the "second trial." It is practical, economical, safe, and pleasing to the eye; in fact, the outline was determined not a little by the general effect, keeping in mind certain well-known principles.

NOTATION.

- h = height of dam in feet —assumed as 1;
 t = width of top of dam in feet —equal to 0.1 h ;
 w = specific gravity of water —equal to 1;
 m = specific gravity of masonry —assumed as $2\frac{1}{2}$;
 P = total spec. grav. water pressure on dam above any plane in question;
 W = total spec. grav. weight of masonry above any plane in question;
 d = depth of water above the plane in question; or depth of section considered, from top of dam downward.

CALCULATION.

Fig. 16 represents the second and final design. (The first design is not shown, but had a greater width at the A' level and contained about 7 per cent. more masonry.) It is to be noted that in the following

Fig. 16.—Author's Type of Dam.—Unit Dimensions.

calculations the *horizontal* position of the center of gravity of the masonry W above any plane in question is desired, but not the vertical position; likewise, the *vertical* position of the center of pressure of the water pressure P , above any plane, is required. The vertical component of P , acting downward on the sloping up-stream face, will be neglected. This is on the side of safety, as, if considered, it would throw the line of resultant pressure for "full reservoir" inward toward the center of the middle third. Calculations will be made of the forces *above* the respective planes A' , B' , C' , D' and E' , taken in order. In other words, the structure is considered as cut successively by these planes and the problem consists in finding the point of application of the resultant force on each plane, (a) for reservoir empty, and (b) for reservoir full. Connecting all the (a) points gives the line of resultant pressure when empty, and connecting all the (b) points gives the line of resultant pressure when full.

A' Level.—This plane is $0.2 h$ below top of dam. Considering one section-foot of dam, and the specific gravity of the masonry equal $2\frac{1}{2}$, we have the acting forces as shown in Fig. 17, in which W_1 and W_2 act alone (above the plane) when the dam is empty, and the force P is added when the dam is full. Or, we may consider $W_1 + W_2 = W$ acting vertically through the center of gravity of the total section above A' , cutting the base at e and being resisted, when empty, by the equal and opposite force R_1 . But when the reservoir is full, the added force P will make the resultant take the direction of , cutting the base at f , and being resisted by the equal and opposite force R_2 . Note that the point o is the intersection of the vertical force W with the horizontal force P , and that, relatively,

Fig. 17.

$W_1 = 2\frac{1}{2} (10 \times 20) h^2$, acting vertically through center of rectangle;
 $W_2 = 2\frac{1}{2} \left(\frac{.035 \times .20}{3} \right) h^2$, acting vertically $\frac{2}{3} \times .035 h$ from left face of parabolic spandril. Hence,

$W = W_1 + W_2 = 2\frac{1}{2} \left(\frac{.335 \times .20}{3} \right) h^2$, acting vertically .0063* h to right of

W_1 , that is, through the point o .

$\therefore \frac{1}{2} d^2 = \frac{1}{2} (.2 h)^2 = .02 h^2$, acting horizontally .06 $\frac{1}{2} h$ above A' . Taking moments, we find the distance $ef = .06\frac{1}{2} h \frac{P}{W} = .0256 h$. It is to be noted that both resultants intersect the A' base well within the limits of the middle third.

B' Level.—This plane is $0.4 h$ below top of dam and is calculated in the same manner as the preceding. Note that W_1 includes W_2 and that W_2 includes W_3 . Then, relatively,

$W_1 = 2\frac{1}{2} (10 \times 40) h^2$,

$W_2 = 2\frac{1}{2} \left(\frac{.14 \times .40}{3} \right) h^2$,

$W = W_1 + W_2 = 2\frac{1}{2} \left(\frac{.44 \times .40}{3} \right) h^2$,

acting vertically through o' , .0293 h to right of W_1 . Hence, R_1 acts .0793 h from left hand face or .0007 h inside of the middle third. For a dam 100 ft. high this amounts to only $\frac{1}{8}$ inch in a total width on the B' level of 24 ft.—an amount insignificant.

$\therefore \frac{1}{2} d^2 = \frac{1}{2} (.4 h)^2 = .08 h^2$, acting .13 $\frac{1}{2} h$ above B' level. Taking moments in the case of the full reservoir

we find the distance $ef = .13\frac{1}{2} h \frac{P}{W} = .0779 h$.

Fig. 18.

C' Level.—In Fig. 19, $W_1 + W_2$ is the relative weight of the masonry above the B' level, while W_3 is the relative weight of the trapezoidal section-foot between the B' and the C' levels. The vertical arrows indicating

* $.0063 = \frac{.0605 W_1}{W_1 + W_2}$. See page 295 for determining the position of the center of gravity of two or more parallel forces.

cause in the former case the deflection will extend down to the while in the latter case it will extend only as low as *bb*. Hence, stresses are set up between adjacent sections, tending to decrease turning moment for the higher sections, near the middle of the dam.

The quantities in this table are expressed, generally, in terms of h , the height of the standard type, Fig. 16. If it is desired to express them in terms of t , the width of top of dam, we have only to substitute the values of h and h^2 expressed in terms of t and t^2 . Thus,

$$\text{as } t = \frac{h}{10}$$

$$\text{and } t^2 = \frac{h^2}{100}$$

we have, $h = 10t$
and $h^2 = 100t^2$.

We may therefore use with this table the top width instead of the height h .

See, also, Table 4.

Fig. 23.

Note.—Area of up-stream face is given in order to estimate the quantity of material in the facing.

EXCERPTS AND REFERENCES.

Periyar Dam and Irrigation Works, So. India (Eng. News, 1901).—Illustrated, with section of dam. Article contains a table of principal dimensions of Periyar dam as compared with those of other large dams over 150 ft. in total height, as follows:

Dam Name	Depth of Water, Ft.	Ht. Above Base, Ft.	Top Width, Ft.	Base Width, Ft.	Area Profile, Sq.Ft.	Top Length, Ft.	Material.
N. Y.	150.	219.	18.	200.	28400.	2240.	Stone.
.....	155.	176.	12.	138.5	10772.	1200.	Conc.
.....	164.	170.6	9.91	161.	10712.	328.	Stone.
.....	162.3	170.33	14.75	154.5	11596.	546.	Stone.
.....		170.	20.	176.	16660.	700.	Conc.
.....	153.54	164.24	35.73	144.29	16349.	925.	Stone.
.....		161.43					Stone.
.....	137.9	156.82	16.40	126.98	6780.		Stone.
.....	147.64	154.2	49.22	216.5	18708.	771.	Stone.

New Type of Masonry Dam (By Geo. L. Dillman. Trans. A. S. C. E., Vol. XLIX).

Five Cross-Sections of the High Earth Dams of the World (Nov. 28, 1901).—Illustrations of 17 dams, giving sections, of core wall, etc., including: The earth portion of New Croton dam, masonry core wall, water slope 2:1; San Leandro Dam, masonry core wall, water slope 3:1, down-stream face 2:4:1; Turner's Embankment, Liverpool (ht. 105 ft.; clay wall extending down 90 ft. into sand, earth, stones, gravel and face 3:1 with 15" pitching); Titicus Dam, N. Y. (ht. 100 ft., masonry wall, down-stream face 2.5:1, water face 2.4:1 with 12" and 18" paving).

Cheesman Dam and Reservoir (By C. L. Harrison and S. H. Harrison. Trans. A. S. C. E., Vol. LIII).—See page 131 of Transactions for cross sections of the following dams: New Croton, Lake Cheesman, Periyar, Furens, Villar, Ban, and Sweetwater dams—in the same order as given, beginning with the highest.

Dams With Concrete Foundations, at Redridge, Mich. (Eng. News, 1901).—Illustrated.

Empirical Formula for the Length of Waterways (By J. P. Frizell. Eng. News, Aug. 8, 1901).—For discussions, see Eng. News, Sept. 5 and 12, 1901.

High Earth Dam, Cal. (By B. Bassell. Eng. News, 1901).—Illustrated, with very complete description of method of construction, rolling, etc.

Practice in Hydraulic-Fill Dam Construction (By J. D. Dillman. Trans. A. S. C. E., Vols. LVIII and LX).

Review of Dam and Reservoir Failures in the U. S. (By Eng. News, June 19, 1902).—Ten listed under "Insufficient Overtopping;" 10 under "Failures Due to Water Leaking and Through Embankments;" 6 under "Failures of Reservoir under "Embankments and Walls Undermined When Built of Yielding Material;" 6 under "Poor Workmanship or Construction;" 4 under "Ice Pressure;" 8 under "Miscellaneous or Unexplained." In addition to the above, 48 other failures of dams and reservoirs are referred to, the causes of failure being unrecorded.

Concrete as a Core for Dams and Reservoir Embankments (Eng. News, 1903).

Design for Hollow Reinforced-Concrete Dams (By H. W. Foster. Eng. News, Dec. 24, 1903).—Illustrated.

Stability of Surcharged Masonry Dams (By E. Sherman Gould. Eng. News, Mar. 3, 1904).

Rubble Concrete Dam for the Atlanta Water & Electric Power Co. (Eng. News, July 7, 1904).—Illustrated section of roadway portion of dam with graphical determinations of resultant pressures. "The advantages of rubble concrete for many kinds of masonry work, and particularly for massive structures like masonry dams, are gradually being recognized by engineers. In many cases where large yardage of masonry is required the use of rubble concrete will effect a saving in time and cost over rubble masonry work or fine concrete work. As an illustration, rubble concrete composed of 40% large stone and 60% of 1:2½:5 concrete requires 7% of the volume to be of cement, while rubble masonry composed of 65% large stone and 35% of 1:2½ mortar requires 10% of the volume to be of cement."

Investigation of Stresses in High Masonry Dams of Short Spans (By G. Y. Wisner and E. T. Wheeler. Eng. News, Aug. 10, 1905).—Relates to the proposed curved Pathfinder dam (cross-section: height 210', top width 10', bottom width 94', up-stream batter 0.15, down-stream batter 0.25), with diagrams giving results of calculations.

Earth Dams with Concrete Core Walls (By Clemens Herschel. Eng. News, Sept. 7, 1905).

Computation of Height of Backwater Above Dams (Eng. News, Nov. 1, 1906; also Nov. 29, 1906, with tables).

Large Reinforced-Concrete Dam at Ellsworth, Me. (Eng. News, May 23, 1907).—Illustrated section; 64 ft. high.

Large Electrically Operated Gates for the Roosevelt Dam, Ariz. (By F. W. Hanna. Eng. News, Mar. 30, 1907).—Illustrated.

Electrically Operated Service Gates for the Shoshone and Pathfinder Dams (By F. W. Hanna. Eng. News, Jan. 2, 1908).—Illustrated.

Reinforced-Concrete Diaphragms for Earth Dams (By B. M. Hall. Eng. News, Feb. 6, 1908).—Illustrated.

Combination Dam and Bridge of Reinforced Concrete (Eng. News, April 9, 1908).—Illustrated.

The Design of Buttressed Dams of Reinforced Concrete (By R. C. Beardsley. Eng. News, April 23, 1908).—Illustrated.

Progress on the Roosevelt Dam; with Cost Data (By C. W. Smith. Eng. News, Sept. 10, 1908).

Movable Dams and Lock at the Power Plant on the Chicago Drainage Canal (Eng. News, Nov. 12, 1908).—Illustrated.

Cast-Iron Sluice Gates for the Fens Gate Chamber, Charles River Basin, Boston, Mass. (By W. H. Sears. Eng. News, Feb. 25, 1909).—Illustrated.

Investigations of the Saturation of Earth Dams (Eng. Rec., Aug. 21, 1909).—Results of experiments by Desmond Fitzgerald: 1. Clay banks are more completely saturated than well-drained banks. 2. Clay banks are more slowly saturated and part more slowly with their water of saturation. 3. In high banks it is unsafe to have nothing but clayey material, a down-stream section of well-drained material being essential.

Partial Failure Through Undermining of the Zuni Dam, New Mexico (Eng. News, Dec. 2, 1909).—Combined hydraulic earth fill, 60,120 cu. yds., up-stream section; and rock fill, 40,160 cu. yds., down-stream section. Up-stream: slope 3:1, rock rip-rap 18 ins. deep on gravel 12 ins. deep. Down-stream: slope 1½:1. Illustrated. The spillway, south abutment and extreme south end of dam were undermined by the passage of water underneath a cap of lava rock which flanked the dam and extended beneath the spillway.

The Eastwood Multiple-Arch Dam (Eng. Rec., Jan. 15, 1910).—Abstract of article by John S. Eastwood, in the "Journal of Electricity, Power and Gas," Oct. 30, 1909. The Hume-Bennett dam consists of 12 arches, each 50-ft. span, resting on 13 buttresses, the end walls of the last buttress at each end being extended into the opposite bank as a core wall, as they are above the normal water line and have no water load. The elevation of the water line is 5,300, that of the crest of the middle six arches is 5,303, and the remainder of the crest to the ends is 5,304 ft. above mean tide level. This allows a 330-ft. crest for any freshet that may occur when the spillway flashboards were accidentally left in their openings. The entire structure

rests on sound bedrock. Mr. Eastwood found that to give the required stability with the greatest economy it was desirable to build the top 16 ft. of the dam with vertical arches, and all arches up to 20 ft. high at the spring line were built vertical. All arches higher than 20 ft. are carried vertical to within 16 ft. of the top at the crown line, and then slope to the foundations at an angle of 32 deg. The arch ring thickness is increased as required for the water pressure. All of the vertical part of the arch wall is 18 in. thick; the wall increases in thickness from this point at the rate of 1 ft. to each 24 ft. vertical, or a little more than required for water load. The buttresses are all 2 ft. thick at the top and project 8 ft. from the inside spring line to the down-stream end, all corners being clipped. The batter of the down-stream end is 5 in. to 1 ft., and of the sides 1 in 24 to the base on each side. Each buttress is finished on its down-stream end with wing buttresses or counterforts. The 12 spillway openings are located in the three middle arches of the dam, the openings being 5 x 8 ft. each, to be closed to any desired height by means of flashboards. The structure was reinforced throughout when necessary by means of railroad iron scrap and old logging cable. . . . The buttress forms consist of 2 x 4 in. studding set about 20 in. apart on centers and spliced where not long enough to reach the top; a framework was first built and lined with 12-in. lumber of 10 and 12-in. widths, lightly nailed to the inside of the studs, the studs being braced to the trestle. The shapes of the counterfort forms were such that they braced themselves when once boarded up. The arch forms were built up from the bottom, using 2 x 4-in. studding and $\frac{1}{2}$ x 6 in. stuff nailed on double.

Crushed granite was used for the coarse aggregate, the crusher-run being mixed with sand from an adjacent pit; the mix was approx. 1 : 2 : 4. The forms were not removed for at least a week after the concrete was laid, and the walls were kept wet by a night watchman and a day crew. A union of the different day's work was made by scarifying the surface of the old work and washing off with a hose; dry cement was then sprinkled over his surface and concreting begun, a few batches of concrete with excess of mortar being laid in contact, the work being carried up as nearly level as possible. The junctions of the walls were made on the center of buttresses, the reinforcement being left protruding to tie them together. . . . The

water face and the parts of the down-stream face were plastered, the water face with two coats of 1 to 1 $\frac{1}{2}$ cement plaster and selected sand and a wash out of neat cement on the bases of the middle arches. A base seal of mortar was placed along the line of contact with the rock. . . . The

structure contains 2,207 cu. yds. of concrete and was built in 114 days. All parts of dam are in compression, max. stress 187.5 lbs. per sq. in. (safety factor 16) being at bases of arch rings. Max. stress in shear, 50 lbs. per sq. in. Rates of overturning, 1 : 3.6. . . . Cost of dam, including plastering, about \$21 per cu. yd. or \$46,000 for the structure; cement costing a little over \$5.00 per bbl., delivered.

Arched Masonry Dam at Las Vegas, N. M. (By C. W. Sherman. Eng. News, Oct. 27, 1910).—Description and illustrations. Also contains a table of 23 curved masonry dams, giving max. height, base thickness, top thickness, max. stress in arch, radius of up-stream face, top length, character of rock, date of building.

Movable Dams on the New York State Barge Canal (Eng. News, Dec. 8, 1909).—Description, with 14 illustrations, of the type of dam known as the ledge dam with the Boulé gates.

50.—FOUNDATIONS.

General Discussion.—Equally as important as the superstructure, is the structure or foundation. This may be defined as that part of the structure designed to carry and distribute safely the forces from the superstructure to the *foundation bed*, and *vice versa*, with resulting stability and no injury or undue stress in any part. Good foundation work in both design and execution is less dependent on theory than structural work in design. It has to draw mainly on practical experience in the particular work at hand, being largely tempered of course with good judgment and certain well-known, established principles.

In the design of any structure we must know, and keep clearly in mind, the nature of the forces, "hence it is necessary in designing foundations to know: (1) the nature of the superimposed loads, (2) the nature of the foundation bed, and (3) the nature of the reactions, at the foundation bed. The first may be calculated with a reasonable degree of accuracy, assuming the foundation and foundation bed to be *relatively rigid*; the second is one of equally accurate determination; while the deduced stresses on the foundations, and the resultant reactions at the foundation bed, are proportioned to the loads above. If now for any reason *unequal settlement* takes place, new stresses will be introduced which may be considered at variance with the calculated stresses in many of the parts, and may work serious injury to the structure as a whole. It therefore lies upon the engineer to so proportion the foundation and foundation bed that not only will each part be sufficiently strong to support the load, *also that they will be relatively strong and rigid*, or at least sufficiently strong to prevent unequal settlement.

Foundation Bed.—In general, the character of material desirable for the foundation bed will take rank in about the following order:

- Solid rock (granite, limestone, sandstone);
- Hardpan or cemented gravel (composed of gravel, sand, and lime or clay binder);
- Gravel and sand (compact and dry, as in gravel pit);
- Indurated clay (hard, dry and well drained);
- Sand (dry);
- Gravel;
- Boulders and gravel;
- Clay and sand;
- Common clay;
- Sand and loam;
- Loam.

This classification, or any other for that matter, may be considered to be more or less elastic, depending (1) upon the amount of moisture present; (2) upon the lateral confinement of the material; (3) upon the underlying strata; (4) upon the nature of the superimposed loads.

Various classes of material for foundation bed will be discussed in the following:

Solid Rock.—Granite, when tested in small cubes exhibits a safe-crushing strength of, say, 12000 lbs. per square inch; sand and trap, not less than that amount; limestone (and marble), 5000 lbs. Some of the best specimens, however, which have been tested give, respectively, twice the above value for granite, or three times the above value for limestone, or 24000 lbs.; and as the above value for sandstone, or 15000 lbs. With these large specimens, where in reality the blocks are ruptured by stresses, it would be problematical to assign even approximate values for the crushing strength of well-constructed masonry foundations in which the "crumbling resistance" would increase faster than the resisting surface. And, furthermore, it would be mere conjecture to assign an upper limit to the resisting power of rock *in situ* and forming the foundation bed. A good, solid rock bed is the best that can be had, and safely support any structure which man is liable to build upon it. Comparing the foundation bed, it should be leveled or "stepped" so that the planes shall be normal to the acting forces. All perishable material should be removed and the exposed surface of the

rock should not be so smooth as to unsafely decrease resistance to sliding of the foundation above. Especially should this be looked after in the case of a submerged pier or of a dam, where the lateral pressure, due to the current of the stream, or to ice, logs, or hydrostatic pressure, would be considerable.

A bed-rock foundation is not always easily obtainable on account of its depth below the ground surface or, in marine work, below the water surface. It is therefore often more economical to choose for a foundation bed a poorer character of material not so deep, thereby saving considerable in excavation but requiring, generally, a more expensive foundation "footing" (see Figs. 1, 2 and 3). Hence it is that often after the excavation for the foundation is started the plans are changed when it has become evident that a stratum has been reached that is "good enough" for all practical purposes; or, on the other hand, when the expected stratum as revealed by the borings does not meet the requirements, and another stratum at greater depth is decided upon. (Excavation processes are described farther on.)

1.—ACTUAL BEARING PRESSURES ON BED ROCK.

Foundations of New Croton Dam.—Calculated pressures limited to 15 tons per sq. ft. at base of dam on rock surface, the resultant pressure being kept within the middle third of section.

Manhattan Life Building, New York City.—Pressure at base of caissons on bed rock, 10.8 tons per sq. ft.

American Surety Building.—Pressure at base of caissons, $7\frac{1}{2}$ tons per sq. ft.

Gilender Building.—Pressure at base of caissons on bed rock, 12 tons per sq. ft.

(b.) *Hard-Pan.*—Next to solid rock there is no better material for foundation bed than cemented gravel or hard-pan. When well cemented, and in thick and extensive beds, it is capable of sustaining safely without injury and with comparatively slight settlement, a quiescent loading of 10 tons per square foot ($= 138.8 \times 8$ lbs. per square inch).

(c.) *Gravel and Sand.*—Large, thick beds of well-compacted gravel and sand, free from wash by the action of water, can generally be counted on to sustain about 8 tons per square foot of quiet loading, or equal to 111.1×1 lbs. per square inch. For such a loading, however, the foundation bed should be at least 10 or 12 feet below the surface of the ground, and the under strata must be firm.

(d.) *Indurated Clay.*—By the term "indurated" we mean the hard variety, usually containing in sufficient quantities such binding materials as carbonate of lime, silicates of aluminum and magnesium, iron oxides, etc. When in the natural bed, at considerable depth, and free from the softening action of water, this material may be loaded safely to 6 tons per square foot (equivalent to 83.3×3 lbs. per square inch). If it contains a proper intermixture of gravel and sand it approaches hard-pan, and the bearing power is increased.

(e.) *Dry Sand.*—Under the most favorable conditions, that is, where the material is confined as in a deep trench and not allowed to spread out from the pressure above, and also where it is reasonably dry and free from wash, sand will easily support a load of 4 tons per square foot ($= 55.5 \times 5$ lbs. per square inch). For large buildings, however, where unequal settlement to any considerable extent would be liable to produce cracks in the masonry walls, the maximum limit of allowable pressure should be fixed at 3 tons per square foot. $2\frac{1}{2}$ tons or even 2 tons is quite common practice under ordinary conditions of wetness, but where there is no wash from running water. For the above conditions the underlying strata must of course be firm. Where the amount of settlement is of minor importance there is really no practical limit to the bearing power of sand, hence the wide range of values assumed. In some instances 10 tons per square foot has been exceeded.

2.—ACTUAL BEARING PRESSURES ON SAND.

Washington Monument, Washington, D. C.—Pressure at base resting on sand bed 3 ft. thick, about 11 tons per sq. ft.; and with wind pressure added, about 14 tons.

Piers of Brooklyn Suspension Bridge.—At base of piers, 44 ft. below bed of river, pressure on layer of sand 2 ft. thick resting on bed rock, $5\frac{1}{2}$ tons per sq. ft.

St. Paul Building, New York City.—Continuous grillage over entire area. Pressure on compact sand, 3.2 tons per sq. ft.

World Building, New York City.—Inverted arches over continuous concrete footings. Pressure on dense, fine sand, 4.7 tons per sq. ft.

Spreckles Building, San Francisco.—Continuous grillage. Pressure on dense, wet sand, $2\frac{1}{2}$ tons per sq. ft.

(f.) *Gravel*; (g.) *Boulders and Gravel*.—Some very important structures are found on these classes of material, both above and under water. If properly prepared and protected from lateral bulging and wash such a foundation may be loaded with 4 tons per square foot ($= 55.5 \times 5$ lbs. per square inch). If, further, it is compacted with dry or moist sand not subject to wash, the bearing power will be increased, say to 6 or 8 tons, depending upon the binding quality of the material and on local conditions; if a moderate quantity of clay is intermixed with the sand and the resultant matrix is sufficient to fill the voids of the gravel the higher value (8 tons) may be used with safety. Such a material if thoroughly hardened would form hard-pan.

3.—ACTUAL BEARING PRESSURES ON GRAVEL.

Piers of Cincinnati Suspension Bridge.—At base of piers, 12 ft. below low water, pressure on gravel bed (neglecting skin friction of piers), 4 tons per sq. ft.

(h.) *Clay and Sand*; (i.) *Common Clay*.—Ordinary soft clay or clay and sand, when wet, is subject to considerable displacement if heavily loaded; and under ordinary conditions it is best not to allow more than 1 ton per square foot ($= 13.8 \times 8$ lbs. per square inch) for important buildings where much settlement would be harmful. But this bearing power may be greatly increased by proper drainage or by a close (lateral) confinement of the material, so that well-drained clay or such clay containing some sand may be loaded with 2 tons per square foot. A naturally dry common clay bed of considerable thickness and extent will stand three tons with allowable settlement; and this may be increased to 4 tons for a mixture of sand and clay where the former predominates and the latter is sufficient for a binder. Hard, firm clay unmixed with sand will also stand 4 tons and if mixed as binder with good, coarse sand the bearing power will be greatly augmented. Fine clay and sand when thoroughly saturated with water forms quick-sand.

4.—ACTUAL PRESSURES ON CLAY AND SAND.

Hospital Building, Albany, N. Y.—Clay with some sand. Pressure allowed, 2 tons per sq. ft.

Congressional Library, Washington, D. C.—Yellow clay mixed with sand. Pressure allowed, $2\frac{1}{2}$ tons per sq. ft.

(j) *Sand and Loam*; (k.) *Loam*.—Loam is too spongy and compressible to be relied upon, from an engineering standpoint, to support any structure, and hence the excavation is always carried through it to some firmer foundation bed beneath. It is a mixture of clay, sand, vegetable mould, and decayed animal matter. But when mixed with a large proportion of sand it is less objectionable especially when well tamped. Railway trestle piers which rest on mud sills supported by this material, are frequently subject to considerable settlement.

Practical Tests of Soils.—Where the bearing power of any particular soil is in question it may be tested by loading a vertical timber of given cross-section (the larger the better) and resting on the soil at the bottom of a pit, with a weight equal to or greater than the proposed intensity of loading. Allowance will be made, however, for the results obtained as the element due to loading such a limited area would be excessive.

Selection of Site for Building.—Generally, the site for the erection of a structure is determined from necessity rather than from choice. That is to say, conditions other than those of local character govern and fix the location. But there are many instances where other sites than those selected would have been chosen from pure economy of cost of foundation if direction had been given to its consideration.

Examination of Soil.—The simplest and most satisfactory method of determining the character of the soil is by digging pits. This should be done generally before making estimates and letting contracts, on all important work requiring excavation in general, and including foundation work at no great depth. For the former we may cite railroad cuts, irrigation canals, and waterways in general; while for the latter, may be mentioned dam sites, and sites for bridge piers, buildings, etc. The pits need only be large enough for a man to find room to excavate. Where great depth is required borings must be made.

Borings in Soil.—For soft earth and clay, up to about 100 feet in depth, a common wood auger with levers, turned by hand, may be used. It may have a diameter of $1\frac{1}{2}$ to $2\frac{1}{2}$ inches and be worked on the end of a sectional iron rod easily made by any blacksmith. It is usually started by one-man power, but after being sunk a short distance two or more men may be required. During the process of boring, samples are brought up and recorded together with their distances below the surface.

For the harder strata and at greater depth, artesian well boring tools are employed. (See *Eng. News*, Vol. XXI, page 324, for illustrations.)

Estimating Loads on Foundations.—These loads include:

(1.) Forces due to the weight of the structure itself, so distributed as to conform with the reactions, whether vertical or inclined. This is not always an easy matter, but the principle should be kept clearly in mind.

(2.) The live loads or that percentage of them liable to act in unison to produce maximum stresses in any part of the foundation. The term "live loads" will here be considered to embrace those loads for which the structure was principally designed, as for instance people, furniture and merchandise for buildings, water pressure for dams, etc.

(3.) The wind loads (also other natural forces of an accessory character such as snow, pressure of ice, etc.), considering possible tension in the foundations as well as compression; also shearing.

(4.) Temperature stresses, due to changes in temperature affecting the length of certain principal members confined between parts of the foundation, as for instance in the two-hinged steel arch.

(5.) Impact loads due to moving machinery, as steam engines, steam hammers, dynamos, etc.

For Buildings.—There are two main classes of foundations in use for buildings, namely, continuous foundations, and independent piers. The latter are generally employed where a suitable, natural foundation bed exists only at great depth, in which case the continuous foundation would be more expensive. As more or less settlement always occurs after a building is erected, due almost wholly to the constant pressure of the dead load, it is best to proportion the area of all foundation footings to the dead load only, using a "reduced" and uniform working pressure for same, so that, selecting that pier which we will call the "Index" pier or part of foundation which sustains the least ratio of dead load to total load, we have,

$$\frac{\text{Reduced working pressure}}{\text{Allowable maximum pressure}} = \frac{\text{Dead load stress at footing of column}}{\text{Maximum stress at footing of column}} \dots (1)$$

Under the subject of Buildings, page 822, it will be noted that for high buildings the maximum stress at footing of column is reduced by diminishing the live load for each floor below the top one a certain percentage, as it is not likely that all floors "in column" will be loaded fully at the same time.

It may be stated here that vault shafts running up through buildings should be carried on a separate foundation from that of the main building. Engine and boiler foundations should also be independent.

Care should be taken that the line of resultant pressure at the foundation footing should come well within the middle third if the foundation bed is solid rock, and it should be practically central for any bed which is soft or springy. Eccentricity of loading may unduly increase the intensity of pressure, and also cause tipping, cracking, and perhaps rupture, of the masonry wall.

For City Building Codes, see Table 5, following page.

For Dams.—To save the reader the time and trouble of looking into the matter it will be stated that for a gravity dam with reservoir empty, it will not be necessary to consider any additional stresses in the masonry or on the foundation bed, due to wind pressure against the down-stream face. Assuming a dam 200 ft. high with a base of 69 ft., and considering a wind pressure of 50 lbs. per sq. ft. acting horizontally (with no vertical component), then under the most unfavorable conditions the intensity of stress at either toe would not exceed 9 lbs. per square inch. In calculating the resultant stress due to any pressure at the top of the dam, as for instance logs or ice, it is necessary only to consider the dam as a beam fixed at one end with length equal to the height of the dam and with depth equal to its base, and assuming the neutral axis of the section to bisect the base.

5.—BEARING POWER OF SOILS FOR BUILDINGS.

(Extracts from various City Codes.)

[Loads are in tons of 2000 lbs. per sq. ft.]

New York (1906).—Where no test is made, different soils, excluding mud, at bottom of footings, shall be deemed safe to sustain the following loads per sq. ft.: Soft clay, 1 ton; ordinary clay and sand together, in layers, wet and springy, 2 tons; loam, clay or fine sand, firm and dry, 3 tons; very firm, coarse sand, stiff gravel or hard clay, 4 tons, or as otherwise determined by the Commissioner of Buildings.

Chicago (1907).—If the soil is a layer of pure clay at least 15 ft. thick, without admixture of any foreign substance excepting gravel, the load shall not exceed 1½ tons per sq. ft.; pure clay in layers at least 15 ft. thick, dry and thoroughly compressed, 2½ tons; dry sand, at least 15 ft. thick, and without admixture of clay, loam or other foreign substance, 2 tons; clay and sand mixed, 1½ tons.

Philadelphia (1907).—Foundations of other materials than piles shall be so proportioned that the loads upon the soil shall not exceed the limits for the different kinds of soil than herein given, to wit: Sand and loose gravel, 3½ tons per sq. ft.; dry, hard clay, 3½ tons; cemented gravel, 6 tons.

Cleveland (1907).—Good, sound, natural earth shall not be loaded to more than the following: Gravel and coarse sand well cemented, or rock or hard shale unexposed to the action of air, frost or water, 8 tons per sq. ft.; dry, hard clay or fine sand, compact and well cemented, 4 tons; moderately dry clay or clean, dry sand, 2 tons; soft, wet sand, 1 ton; quicksand or alluvial soils, ½ ton; the sand underlying the City of Cleveland above the lake level, commonly called "quicksand," when drained of its ground water without puddling or disturbing the foundation may be loaded, 3 tons.

San Francisco (1910).—Soft clay, 1 ton per sq. ft.; sand and clay mixed, 2 tons; firm, dry clay, 3 tons; hard clay, 4 tons; loam or fine, dry sand, 3 tons; compact sand, 4 tons; coarse gravel, 6 tons; shale rock, 10 tons; hard rock, 20 tons.

Buffalo (1909).—In no case shall the soil under any building be loaded with a weight greater than 3½ tons per sq. ft. If the soil is composed of other materials than hard clay or gravel then the area of the foundation shall be extended as directed until the pressure is reduced to a safe limit.

District of Columbia (1906).—(Practically the same as N. Y. City Code.) Soft clay, 1 ton per sq. ft.; ordinary clay and sand together, in layers, wet, 2 tons; loam, clay, or fine sand, firm and dry, 3 tons; very firm, coarse sand, stiff gravel, or hard clay, 4 tons, or as otherwise determined by the Inspector of Buildings.

For Machines, Dynamos, etc.—The weight of the machine as a whole is not alone to be considered. A more massive foundation may be required for a light machine than for a heavy machine with the same weight of moving parts. The foundation should be on a natural, hard bed, but where this is not obtainable the foundation itself should be massive enough to absorb the shock or impact of the machine. Manufacturers usually prefer to install their own machines and prepare the foundations, and, where possible, it is best for them to do so on account of their practical knowledge of the requirements of the case.

Types of Foundation Footings:—

Fig. 1.—Least dimensions for ordinary concrete footing under brick or rubble wall or pier. Where more bearing area is required on foundation bed the offset and thickness are increased or the sides of the footing sloped, as in Fig. 2.

Fig. 2.—Concrete footing with or without I-beams, for heavily loaded walls, yielding foundations, or both. One or more of the beams is often imbedded in the concrete to give stiffness and absorb shock due to heavy machinery, as in power houses, etc.

Problem.—Let it be required to design a footing of I-beam construction under a steel column, carrying at bottom of footing a maximum load of 748,000 lbs., and on a soil capable of sustaining 3 tons (6000 lbs.) per square foot.

Solution.—By using formula (1), page 866, we find that the *reduced working pressure* on foundation is, say, 5200 lbs. per square foot, hence the total area of the footing should be $748,000 \div 5200 = 143.8$ square feet, or say a square base of length $B = 12$ ft. Now, tentatively, we may assume that $A = \frac{B}{4} = 3$ ft.; $a = \frac{B}{4} = 3$ ft.; $b = \frac{3B}{8} = 4\frac{1}{2}$ ft.;

$c = \frac{B}{8} = 1\frac{1}{2}$ ft. Then for the bottom tier

of beams each cantilever arm a will sustain a total upward pressure of $5200 \times a \times B = 5200 \times 3 \times 12 = 187200$ lbs., producing a bending moment of $187200 \times \frac{a}{2} = 280,800$ ft.-lbs. Using a fiber stress

of 16000 lbs. per square inch for steel I-beams the above moment calls for either 12 9" 21 lb. beams, 9 10" 25 lb. beams, or 6 12" 31 lb. beams*. The 12" beams are the more economical, while the 10" beams give closer and better spacing and will be adopted. Similarly, for the middle tier of beams, each cantilever arm b will sustain a total upward pressure (neglecting weight of lower tier of beams) of $5200 \times b \times B = 280800$ lbs., producing a bending moment of 631800 ft. lbs., and calling for 5 20" 65 lb. beams. Lastly, for the upper tier, each cantilever arm c will (be assumed to) support one-quarter the total load or 187,200 lbs., producing a bending moment of 140,400 ft.-lbs., and calling for 5 10" 25 lb. beams.

Other proportions may be assumed for the areas of the tiers of beams if it is thought that economy may result.

Coffer-Dams.—A coffer-dam is a fixed enclosure built *in situ* around a proposed foundation for the purpose of shutting out the water during construction of the latter. Such a dam may be formed by building an earth embankment around the site; by constructing a water-tight casing of any material, as iron or wood; by sinking cribs; by driving sheet piling; or by a combination of these methods. In any event there will be more or less leakage, and either hand or machine pumps will have to be installed to keep the site dry.

By Earth Embankment.—A tight dam may be made with gravel and clay, but other soils may be used if there is a matrix sufficient to fill the voids. This construction is used where the water is shallow and quiet or where there is but little current. The width of dam at top may vary from 3 ft. upward, with side slopes of 2 or $2\frac{1}{2}$ to 1. For a depth greater than 5 ft. other methods are generally used. Sometimes sand in bags is employed to good advantage, especially where there is some current.

By Water-Tight Casing.—The casing may be in the form of a large wooden crib with single or double shell. If of single shell, the seams are calked tight, while if the shell is double the intervening space or chamber is packed with clay puddle, to prevent leakage. The size of the shell timbers depends on the depth of water and also on the interior bracing. For coffer-dams in ordinary bridge foundation work, 12"x12" timbers are frequently used, dove-tailed or rather halved at the joined ends or corners. The bracing may extend entirely across the crib from shell to shell, and be replaced by shorter struts abutting against the masonry as the latter inter-

Fig. 3.—I-beam Footing for Independent (isolated) Piers. Beams to be imbedded in concrete.

* See Tables of Properties of I-beams, pages 554 and 556.

cepts it in being projected upward. In designing the shell, remember that the hydrostatic pressure in lbs. per sq. ft. = $62.5 H$, in which H is the depth in ft. below the water surface. (See Dams, page 846.) Thus for a horizontal shell timber of length, say, 6 ft. between interior bracing, and whose center is 30 ft. below the surface, we have, if d equals thickness of shell,

$$\text{Bending moment} = \frac{w l^2}{8} = \frac{62.5 \times 30 \times 6 \times 6 \times 12}{8}$$

$$\text{Resisting moment} = \frac{1}{8} f b d^2; \text{ in which } f = 1000, \text{ and } b = 12.$$

$$\text{Equating, } d^3 = \frac{62.5 \times 30 \times 6 \times 6 \times 12 \times 6}{8 \times 1000 \times 12} = 50.63; \text{ or, say } d = 8 \text{ ins.}$$

The design of such a crib is quite simple under favorable circumstances, but in a swift stream with an uneven bed, part of which may be rock, it offers many difficulties. The bottom of the crib in this case should conform closely with the rock bottom. For a silt bed the bottom of crib should be sharpened to penetrate the silt. Piles may be driven to hold the crib in place. This leads to another construction, namely, that of driving one or more rows of piles and sheathing them, thus obtaining the same result in another way. The piles should be well diagonal-braced where necessary to resist bending, remembering that where not so braced the resisting moment of the section in inch-lbs. is = $0.0982 \text{ diameter}^3 \times \text{allowable outer fiber stress } f \text{ of pile per square inch—say } f = 1000$.

By Sinking Cribs.—A large crib coffer-dam is sometimes formed by sinking several small cribs in line around the site, and planking and calking them on the outside. The cribs are made rectangular, of squared timbers framed in the ordinary manner, and containing cells or chambers, somewhat above the level of the bottom, to be weighted with stone so as to sink into the river bed. Guide piles are often driven for this work. In sinking cribs where there is current two or more clusters of piles may be driven up stream, or auxiliary cribs may be sunk to which are attached adjustable steel cables or "dropping" the cribs into position.

By Driving Sheet Piling.—This is one of the most common methods in use, both in wet ground and in shallow water; and where it can be employed effectively, is simple and cheap. Some of the principal forms of wooden sheet piling are the following:

Fig. 4.—Large Square Piles.

Fig. 5.—Plain Single Sheeting.

Fig. 6.—Double Sheeting.

Fig. 7.—Triple Sheeting.

Fig. 8.—Matched Piles.

Fig. 9.—V-Matched Piles.

Fig. 10.—Tongue-and-Groove Piles.

Fig. 11.—Built Matched Pile.

Fig. 12.—Built V-Matched Pile.

Fig. 13.—Built W-Matched Pile.

Fig. 14.

Fig. 15.

Fig. 16.

Figs. 14, 15, 16.—Details of Wakefield Sheet Piling.

Other forms are in use but they are no improvement over the above. The lower ends of the piles are usually cut on the slant so that in driving they will crowd against those in place and close the joints (Fig. 17). They are also sharpened so as to "broom" if there is solid rock bottom. A good method to secure tight joints is to drive from both ends of the line toward the center and then drive home a good tight-fitting "key" pile. Sheet piles are usually driven between guides or horizontal waling pieces which may be supported by a row of ordinary round piles, or sawed piles, previously driven. After the sheeting is driven it is keyed tightly or wedged in the wales.

Fig. 17.

STEEL SHEET PILING comes in many forms, some of which are composed of standard rolled sections riveted together, while others are special rolled sections not requiring any riveting.

Fig. 18.

Fig. 18 illustrates an interlocking channel-bar piling caisson driven in place and ready for excavating. The piling is that of the Priestedt* type. This piling in place will weigh from 23 to 67.5 lbs. per sq. ft. Piling which will weigh when interlocked about 41 lbs. per sq. ft. will have a moment of inertia of 69.21 and a radius of gyration of 1.6.

Fig. 19.

Fig. 19 illustrated the plain rolled section as manufactured by the United States Steel Piling Co. of Chicago. The actual cost of this piling depends somewhat upon the specifications. If ordered cut to lengths it can be furnished on cars at approximately \$42.00 per net ton. Where corner pieces are required there is a net extra of approximately \$10.00 per net ton for the corners only, and there is also a net extra of \$2.00 per ton for punching each piece with pulling holes where purchasers prefer shop punching, prior to shipment. The above prices are for August, 1906.

* Manufactured by the Priestedt Interlocking Channel Bar Co., of Chicago.

in coffer-dam construction may often be stopped by the puddle, with perhaps an intermixture of straw and gravel if the foundation bed. A more expensive but effective method, and be applied to deep rock fissures, is by grouting. Sometimes tarpaulin coated with asphalt and weighted to the bottom will fact the use of canvas can generally be recommended in various cheap and convenient. The joints of the upper-work should be the seams may be asphalted or greased if desired. The coffer-dam is constructed the water is pumped out and the excavated to a firm foundation bed.

Foundations.—In soft, marshy ground it is often best to use a pile and for permanent construction the piles should be cut off at level below the level of so-called continual saturation, or low water. Many of our tall office buildings, up to 12 stories or more in on piles, as do also many of our large masonry bridge piers. A pile unless specially named otherwise will be assumed to be of

Driving Power of Piles.—Some engineers have claimed that piles driven with the large end downward; and this would be logical that the direct bearing of the lower end were all the supporting the pile received.* But it must be remembered that with the butt and the pile tapering downward it receives considerable vertical along the sides in addition to the largely increased "friction." to its being the most practical way there is another point in driving the small end downward, namely, that generally the soil compactness with the depth below the surface and hence tends to lateral stiffness at the lower end where it is required. This is important where a pile is driven to a hard stratum, through compact materials, thereby acting as a column subject to bending. A column may be considered as "fixed" at the lower end. In driving piles so supported and driven through loose, soft material should not exceed $\frac{1}{4}$ to $\frac{1}{2}$ the allowable load on a short column of the same sectional area. In any case the loading should be limited by the formula† which takes into consideration the resistance at the bottom (see Table 6, following page):

$$\dagger P = \frac{2wh}{s+1} \dots \dots \dots (1)$$

where P = safe load in tons, on pile;
 w = weight of hammer, in tons;
 h = height of free fall of hammer, in feet;
 s = penetration of pile at last blow, in inches.
 In practice to drive a pile ordinarily until the penetration at the last blow is less than $\frac{1}{4}$ inch, using of course a moderately heavy hammer; it is to be taken that the pile itself is not being injured by "brooming" at the bottom, top, or any other part. Many piles are seriously injured by overdriving. An experienced man can tell, generally, when a pile is "driven" by the action of the pile and hammer, and the

Methods.—The main essentials of a pile driver are (1) a hammer and a derrick with vertical (or inclined) leads with guides for the work in, and (3) power to operate the hammer, so that in its strike the head of the pile and ram the latter into the ground. Consider such accessory devices as the explosion of gunpowder on the head of the pile as the hammer descends, because the practical utility of such methods have not been demonstrated.

Precautions.—Under certain conditions, such as to prevent subsequent uplifting, the pile should be driven butt end downward, as when the sub-stratum is quick-sand. If the pile is supported more or less throughout its length by the resistance of the material through which it is driven unless it be supported laterally, a pile may assume all the conditions of strength of a short strut to that of a long column with round ends, as when driven through silt to a solid rock bed.

Formulas.—On's formula for drop-hammer. For steam-hammer, $P = \frac{2wh}{s+0.1}$.

Safety.—For safety of 6.
 For description of Pile-pulling machines, see *Eng. News*, April 16, 1903.

The drop-hammer.—This may consist of a heavy block of oak when some hastily improvised machine is desired, but the cast-iron ram as shown in Fig. 17 is the type quite universally employed. In the illustration the hammer *h* is engaged by the nippers *n*, and is released when the latter are drawn up against the wedge *w* fastened to the guides *g*, at the top of the derrick. The hammer may also be released at any height below the top by pulling a tripping rope attached to the nippers. The hammer line or hoisting rope *r* runs over a 10" to 18" sheave (2 sheaves are fixed at the top—one for the hammer line and the other for the pile line) and can be operated either by horse power or by hoisting engine. These hammers weigh from 1200 lbs. upward, 2000 to 2500 lbs. being a very satisfactory medium weight. Greater speed can be obtained by the use of a hoisting engine with a friction clutch or friction drum, so that the rope and hammer may be released by the engine driver at any moment. In such a case the hammer rope is fastened permanently to the hammer which is level on top, instead of being depressed as in Fig. 20. It is to be noted that the hammer should be heavier for this method as it has to "overhaul" the hammer rope in its descent. Such hammers weighing 3500 lbs. are very efficient.

FIGS. 20.
Drop-Hammer
with Nippers.

The steam-hammer.—Fig. 21 is an illustration of an improved type of steam-hammer† with a "gravity" action. The total machine, which may

* For any other drop the bearing is proportional. Thus, for 15 ft. drop, multiply by $\frac{3}{4}$; for 25 ft. drop, multiply by $\frac{5}{4}$; etc.

† The Warrington steam hammer as manufactured by the Vulcan Iron Works, Chicago. The first steam hammer for pile driving was applied by James Nasmyth in 1845.

weigh as much as 5 tons, is suspended from the top and between the leads or gins of the derrick, like a common drop-hammer; but in this case it is allowed simply to *rest* on the pile to be driven. The ram *h*, whose weight is about half that of the total machine, slides vertically on four circular guides and is connected to a piston rod operated from the cylinder *c*. Steam is led into the lower part of the cylinder through a flexible tube, thus raising the ram which is then allowed to drop by its own weight. The amount of "drop" may be lessened if the cylinder is double acting.

The derrick.—The ordinary pile driver derrick is a simple affair consisting of two upright leaders with guides for directing the hammer (Fig. 20), and supported by a framework (for fore-and-aft and lateral bracing) resting on a platform or horizontal frame. The frame may rest on a scow, on a car, or on rollers. If on a scow, it is usually fixed; on a car, it is allowed to swing laterally around a vertical pivot; on rollers, it is given forward and lateral movement by using two sets of wooden rollers, one above the other, at right angles to each other. A *tilting* driver for driving batter piles may be constructed by allowing the leaders to swing on a horizontal pivot attached to the A-frame of the derrick near the top; or by pivoting the whole derrick frame on V-bolsters which will allow lateral tipping. Ratchet devices may be used for tilting the leads or the derrick frame, and holding them in position while driving the piles. The following dimensions may be taken as mere "hints" for design of scow and heavy land derricks: For a 60-ft. derrick, leads 8"x10"; guides 4"x4" sheathed with 4"x½" iron; spreads (lateral) 8"x10" for height of 55 ft. and total base of 18'; ladder strings (fore and aft) 6"x12" for height of 60' and base of 18 ft.; horizontal bracing 6"x8" to 8"x10" (the latter supporting platforms); diagonal bracing 4"x12"; platform frame 12"x12" and 12"x14"; caps (for supporting sheaves) 20". For a height less than 60 feet the dimensions may be proportioned out as the square root of the height; thus, for a derrick 30 ft. high multiply $\sqrt{3}$ or $\frac{1}{2}$. Less amount of bracing is of course needed for a low derrick than for a high one and where it is not over 20 or 25 ft. the diagonal bracing not required. For a steel frame, proportion the members for equal strength and stiffness to the above. A car-derrick may be made to hinge the foot of the ladder strings and lie flat when not in use. If a light, portable land driver is required the above proportions may be reduced.

The power.—This may be either man, horse, steam, gas, hydraulic, pneumatic, or electric. The first named is now only employed in driving sheet piling, and to a limited extent. The horse is used frequently in outlying districts where it would be expensive to ship a hoisting engine for the needed amount of work to be done. Steam is mostly employed, and usually the hoisting engine or by operating the steam hammer (see page 872). Hydraulic pressure may be used for driving piles for foundation work in submarine tunnels where a steady pressure, without shock, is absolutely necessary. For a large amount of work requiring several drivers, electric power, delivered from a central plant, has proven economical. Fig. 22 is a light, portable steam pile driver for height up to 50 feet. Diagonal bracing may be used if deemed advisable, but should not be added, to increase the portability, unless the work is heavy and demands it. Driving is often assisted by the water jet.

Water jet.—If the soil is sandy great assistance in driving piles may be rendered by attaching the end of a hose pipe to the foot of a pile and playing a stream of water into the sand as the pile descends. If the material is pure sand, driving often becomes unnecessary, the pile settling readily under the weight of the hammer. In some cases a driver is not used at all, the pile being driven down by bringing some other weight to bear

Fig. 21.
Steam Pile
Driver. -

Fig. 22.
Light, Portable
Land Driver.

upon it, as by block and tackle or by lever. Softer wood for piles can be used in such cases than would be required for ordinary driving.

Pile shoes.—These may be used in hard driving to prevent brooming of pile. The shoe may be of cast iron or steel, usually fitted to the point of pile after the latter has been sharpened or shaped to receive it. Cones made of sheet steel are sometimes used. Provision should be made, by lugs or straps, for spiking or bolting the shoes to the piles. Shoes should have either a point or an edge, for penetration.

Common Pile Foundations.—There is danger in driving piles too close. Instances are frequent when piles already driven have been weakened considerably by subsequent too-close driving. 2'-9" centers is about as close as ordinary piles should be driven, and 3'-0" is much better; but local conditions sometimes demand a minimum spacing of 2'-6" or even 2', especially if the piles are small.

Piles should be driven to firm foundation, and it is sometimes necessary to drive them in "tandem" or one above the other to reach a suitable supporting soil. Fig. 23 shows the dowel connection used for splicing same. Piles spliced in this manner have been driven considerably over 100 ft. in depth.

Fig. 23.
Dowel Splice.

Cutting off piles.—Grades for cutting off piles are given by, say, driving a tack in the side of the pile either at the desired level or at certain established distance below it. The cut-off is made with a cross-cut saw resting on two short horizontal guide sticks nailed on opposite sides of pile, with top edges at grade. For cutting off-piles *under water* there are several methods: (1) The above method may be employed sometimes during *absolute* low water, by sawing off two or three feet below the surface, provided the cut-off is near the river bottom; (2) under the same conditions as above it may be advisable to cut off all the piles just above the surface and then nail horizontal guide strips on which to suspend a "gage" saw operated by hand and which will cut off the piles at the true level a certain distance below the guides; (3) a circular saw fixed horizontally at the lower end of a vertical shaft operated from a scow, may be used; (4) if the water is too rough or deep and greater care is required it is best to cut the piles off above water as in method number (2) and construct a level platform on which to operate the circular saw, say 4 ft. diameter, from a movable machine (a pile driver is sometimes rigged up for this purpose) mounted on rollers.

Foundations on piles are of many kinds and are discussed under Caissons, and what follows.

"Dead-Men."—These are short piles sometimes "planted" through soft material to a firm bed and packed around the sides with gravel or sand, wet and well tamped. They should be well braced laterally.

Iron Piles.—These are cast iron, wrought iron and steel, being best (most durable) in the order named. Cast iron piles may sometimes be used to advantage in hard-driving soil where a wooden pile would broom and where the ground becomes alterably wet and dry. Steel shapes, as I-beams, may be used in wharf construction (fresh water) where considerable lateral thrust has to be resisted. They should be coated with asphalt before driving.

Screw Piles.*—A screw pile consists of a cast iron shoe, shaped something like a cartridge, surrounded by about $1\frac{1}{2}$ turns of spiral disk thread 5 feet more or less in diameter and mounted on the lower end of a vertical shaft which, when turned, screws the pile into the ground. The shaft is usually of steel and about $\frac{1}{6}$ the diameter of the screw. Screw piles are particularly adapted to soft soil, but are seldom used in this country excepting for wharf work, anchoring beacons, and light-house construction. Their use in bridge foundations has been extremely limited. The circular area of the screw presents resistance against an uplifting as well as downward force.

Disk Piles.†—A circular "disk" of cast iron fastened to the lower end of an iron shaft and sunk by the water jet (see page 873) is the usual form

* See Eng. News, Oct. 15, 1903.

† See Trans. A. S. C. E., Vol. VIII, page 227-37; Coney Island Pier

e. The thickness of the cast disk may be, say, about one-third its diameter, the latter being proportioned to the required bearing area, and not out 2 ft. for an ordinary shore-sand foundation. The diameter of the disk is proportioned to the superimposed loading and may be equal to the thickness of the disk, more or less. Screw piles are more common than cast disk piles.

Piles.—Sand piles are formed by driving ordinary piles, pulling them out immediately filling the hole with wet sand, well compacted in place. Such piles if well constructed will usually have a greater bearing power than the wooden piles withdrawn, provided, of course, the sand is firm enough to give lateral support.

Concrete Piles.—A concrete pile may be constructed in a similar manner to a cast pile, just described—differing from a concrete pier in that it has lateral support from the soil, which the pier does not. But the concrete pile, in place, is either (1) a concrete core enclosed in a metal shell, or (2) a steel reinforcement encased in concrete (the ordinary concrete-steel column). In either case the piles are driven with the drop- or the steam hammer; or they may be sunk with the water jet, by a small metal tube centrally located in the pile, terminating at the point of the pile; or the water jet may be used to assist the driving. Under this heading we will include only those piles encased in a metal shell, and then follow with a discussion of concrete piles, under a separate heading.

Jet Concrete Piles.*—Fig. 24 illustrates the method of constructing a concrete pile by the water jet method. The pile is of sinking same by the water jet. The pile is a telescopic shell (similar to a collapsible drinking cup) is assembled at the surface. The pile is to be sunk; the shoe, with a nozzle, is attached to the water pipe, and under pressure of 40 lbs. more or less, the water jet is forced through the nozzle into the sand; as the pile sinks, the sections sink they are filled with concrete, and the "spreaders" are introduced at the joints to prevent the sections from separating. The process is simple and effective. The piles can be sunk to any considerable depth in sand, and they form a safe and permanent foundation.

Fig. 24.

The process is simple and effective. The piles can be sunk to any considerable depth in sand, and they form a safe and permanent foundation.

Shell Concrete Piles.*—The finished pile consists of a metal "shell" of 20 sheet iron, driven into the soil and then filled with concrete. It is driven by inserting into it a tightly fitting iron "core" which is considered as the "temporary pile" and which is driven in the same manner by the drop or the steam hammer, and with a follower to protect the head of the core from damage. After driving, the metal core is collapsed (made to less than its original diameter) and withdrawn, leaving the metal shell in place, which latter is now filled with concrete. The metal shell consists essentially of three main parts, split longitudinally, the outer "halves" being split by the third, acting as a wedge between them. When the key is lowered the halves are spread apart as in Fig. 25. When raised, the halves are ready to be withdrawn. The diameter of the shell is 6 ins. at the point and, say, 16 to 20 ins. at the top.

Fig. 25.

Reinforced-Concrete Piles.—These may be built in various forms, as circular, (modified) triangular, (modified) rectangular (for sheet piling), etc. Figs. 26, 27, 28 and 29 show simple sections.

Sometimes four more rods are placed intermediately between those shown in Fig. 26, making 8 reinforced rods instead of 4. For rectangular section, the I-beams are often used—3 on each side.

Instead of rods or expanded metal, I-beams are sometimes used, for sheet piling where lateral stiffness is required. The I-beams are connected at intervals by riveted diaphragms.

At the point of the pile the reinforcement rods are brought together, and may be banded with wire, or welded. At the top, the rods are imbedded in concrete; but after driving, the concrete may be picked away and the rods exposed in order to bind with the new-laid concrete for foundations.

Fig. 26.

Fig. 27.

Fig. 28.

Fig. 29.

Fig. 26.—Circular, tapering pile, reinforced with $\frac{1}{2}$ " and $1\frac{1}{2}$ " steel rods, united at bottom of pile.

Fig. 27.—Cylindrical pile, reinforced with expanded metal.

Fig. 28.—(Modified) triangular pile, reinforced with $1\frac{1}{2}$ " steel rods, and $\frac{1}{2}$ " wire ties.

Fig. 29.—"Square" pile, reinforced with 4— $1\frac{1}{2}$ " steel rods with various arrangements of $\frac{1}{2}$ " wire ties. The central hole is for water jet.

Concrete piles are made in moulds. They should be kept sufficiently wet while curing, and away from the sun. In driving, a follower should be used to protect the concrete, at the head of the pile, from injury.

Fig. 30.

Open Caissons.—An "open" caisson is a water-tight box without a top, in which a masonry pier is built and sunk on to a prepared foundation. The sides are detachable from the bottom (see Fig. 30), and hence may be removed after the pier is sunk in place, and used in the construction of succeeding piers. Guide piles are usually driven to assist in sinking the caisson.

The following rules will be found useful in proportioning the thickness of planking on the sides of the caisson, and subject to hydrostatic pressure (taking into consideration the deflection as well as the strength): *Hard woods:* For hydrostatic head of 36 ft. make thickness of planking in inches equal to the unsupported span in feet; for $4\frac{1}{2}$ ft. head make the thickness one-half of the above; for intermediate heads make thickness directly proportional between the two. *Soft woods:* For hydrostatic head of 30 ft. make thickness of planking in inches equal to the unsupported span in feet; for $3\frac{1}{2}$ ft. head make the thickness one-half of the above; for intermediate heads make thickness directly proportional between the two.

In proportioning the uprights, note that for deep caisson work they may be braced by horizontal struts from side to side or from the sides to the built masonry pier.

For the construction of *concrete* piers in open caissons, the wooden forms are built inside and separate from the sides of the caisson—leaving a space between, all around.

For large or deep piers the floor of the caisson may be of two or three courses of 12-inch timber; and the sides may be planked with two thicknesses of planking (the inner course being laid diagonally), or they may be composed of crib timbers dovetailed or halved together and well drift-bolted. Guide piles are sometimes driven in pairs instead of in single line.

Crib Piers.—A crib pier is simply a wooden crib (see page 869) or box constructed of logs or of squared timbers framed and bolted together, and sunk to a natural or a prepared foundation bed, by filling the chambers with gravel, rock, etc. A crib differs from a caisson in that the latter is supposed to be water-tight. The crib may or may not have a bottom. If it is sunk to a natural bed the bottom is omitted (which is the usual form) and the sides are projected downward a few feet below the inner bracing and chamber floors so as to cut into the bed and get a good stable bearing. The bottom of the sides of the crib is sometimes extended by blocking, to conform with the natural bed, especially if the latter is solid rock, in which case the crib is often bolted thereto.

The crib may be of rectangular form (with vertical or inclined sides) or it may have a V-end up-stream, and perhaps down-stream also. The up-stream end should be protected with angle iron or steel rail, against floating ice and logs. In framing the sides, the timbers (say 12"x12") may rest squarely on each other or be separated a few inches; and framed into the cross timbers, say every four feet apart. Interior longitudinal timbers are also framed in, about the same distance apart, forming vertical chambers about 4-ft. square. The bottoms of these chambers are planked, to hold the filling. All the timbers should be securely drift-bolted together. If the crib is designated to support a heavy superimposed load the chambers should be made smaller by increasing the number of longitudinal and transverse timbers.

The crib is usually sunk directly on the bottom, if hard; but if soft, it is sometimes sunk on a prepared pile foundation, and the bottom protected from scour by a deposit of rip-rap. If the crib projects above low water it becomes merely a temporary structure as the timbers are exposed to rot. Crib piers are specially permanent when entirely submerged below low water mark, and when not subject to the attacks of the *teredo* (see page 360). As such, a crib may act as a sub-foundation on which may be constructed a concrete or stone masonry pier.

Pile Piers.—A pile pier is a pile sub-foundation projected upward to support the superstructure direct. It is at best a temporary affair and lacks the lateral stability of masonry. Pile piers and abutments are used largely in every new country where timber abounds, for supporting railway and highway bridge spans, on account of low first cost and rapidity of construction. As Bridge Engineer of a western railroad the writer constructed many of the bridges from end of track, as the latter was laid causing little delay in the tracklaying, and utilizing the construction trains for the transportation of material to the bridge sites.

A simple form of bridge pier consists of two or more rows of piles (5 or more in a row), each row capped with a 12"x14" cap dapped $\frac{1}{2}$ inch and drift-bolted with 1"x20" drift bolts. On top of these caps, cross-caps are drift-bolted to receive the pedestals of the span. The inside rows of piles may be projected up-stream in the form of a V. The rows of piles should be sway-braced with 4"x12" planking, both longitudinally and transversely; secured at the ends, to piles and caps, with screw bolts; and double spiked at intersections with piles. The outsides of piers may be sheathed all around with 3-inch or 4-inch planking, laid longitudinally with butt joints. The nose of the pier may be driven with batter piles and sheathed with iron as a protection against ice and logs. Rip-rap may be deposited around the piles, to prevent scour; also pile clusters may be driven up-stream, as ice breakers or fenders.

Tabular Piers.—Under this heading the writer desires to bring to the attention of the reader a variety of piers which are tubular in form, com-

posed of various materials, sunk by various processes, and occupying various positions when in place. When we say "tubular in form" we mean that they are composed of a tubular "shell" which is lowered into position and filled with, say, concrete or some other equally serviceable material.

Shape.—The circular section is the one most commonly used and hence if the section is uniform throughout, the pier is cylindrical in form; if the section decreases uniformly upward it is conical. Often two cylinders of different diameters (the smaller one above) are joined by a conical frustum. They are usually placed in pairs for supporting bridge trusses, being braced to each other by a web plate, or by horizontal and diagonal bracing. The center pier of a drawbridge may be one large circular cylinder or may consist of, say, 6 or 8 separate cylinders surrounding a central one of larger diameter, all braced rigidly together. When used singly for center piers of draw spans the oval or elliptical section is sometimes preferred.

Materials.—Timber staves, say from 6" to 12" thick and planed with sides radial have been constructed in the circular or "barrel" form similar to the sides of a water tank or a section of stave pipe. The bottom is provided with an iron shoe if it is to be sunk into the soil. Instances are on record where a masonry shell, as of brick, has been used as a tubular pier and sunk into the ground to considerable depths. But the most commonly used materials are the metals—cast iron, wrought iron and steel. Cast-iron shells with metal 1-in. thick, more or less, and with flanges inside for bolting the sections together, present a smooth exterior surface for sinking, and are very durable. Wrought iron and steel are generally preferred. The metal is from $\frac{1}{4}$ -in. to $\frac{1}{2}$ -in. thick and the riveted tubes are composed of sections from 5 to 6 ft. in length. Both butt- and lap joints are used. The cylinders are stiffened at the top with an outside circular angle-iron and the top covered, when finished, with a plate. There is no reason why a reinforced-concrete shell should not prove economical under certain favorable conditions.

Sinking in Place.—The method of placing or sinking the tubes, or their method of support after being placed, often determines the *name* of the pier. For instance, a metal cylinder encasing a cluster of piles is called a Cushing cylinder pier, "Cushing pier," or Cushing pile, named after the inventor of the system. If the same cylinder (or usually two cylinders) is set on a timber platform resting on piles, it is called a "platform pier," platform cylinder pier, or simply a cylinder pier. If it is sunk in the ground it may receive the name of cylinder pier, or "tubular pier." If sunk by the pneumatic process (compressed air) it is called a "pneumatic cylinder," pneumatic tube, or pneumatic pile. Sinking the cylinder in place, in the foundation bed, may be accomplished either by: (1) Weighting the tube with pig iron and excavating inside, whence it descends by overcoming the frictional resistance* on the sides; (2) Dredging, when in water, and loading as before; (3) Pneumatic Process, for great depth under water, excavating in a "working chamber" under compressed air, as with the pneumatic caisson.

Cushing Piers.—Fig. 31 illustrates two styles of casing and two styles of piling ordinarily used for Cushing piers. The wrought-iron or steel cylinders (say $\frac{1}{4}$ " to $\frac{1}{2}$ " metal) are usually placed after the piles are driven and bolted together, but sometimes one of more bottom sections (5 to 6 ft. lengths each) are set up and riveted together in place and then the piles are driven inside of them. Care must be used not to bulge the sides in driving. After the cylinders are set and connected with bracing (at least at the bottom) they are filled with concrete, deposited in layers and thoroughly tamped around the piles. Soft silt, logs, boulders, etc., should be removed (previously) from the bottom and the cylinders should rest on as firm a foundation bed as practicable. The horizontal bracing between the cylinders may be composed of two channels with pin connections to angles or bent plates riveted to the cylinders. They may be connected top and bottom, with tie plates or lattice bars, or be reinforced with plates. Two 10" channels are common for small piers. Adjustable rods, singly or in pairs, are often used for the diagonal bracing, but stiff members are preferred. Howe truss bracing

* The frictional resistance for cylinder piers may vary from about 300 lbs. per sq. ft. in mud, up to as much as say 1500 lbs. per sq. ft. in gravel.

been used considerably in the West where timber is plentiful; that is, diagonal braces are of timber, say 10" to 12", tied with horizontal rods, and upward. The web braces are usually sheathed on both sides with 2-in. planking, projecting well beyond high and low water. One of the best forms of bracing is a web plate connected with the members by vertical angles riveted to it. The web is stiffened at intervals by horizontal angle stiffeners. Much of this description, especially that relating to the bracing, applies to Platform Piers, which will next be described. Plenty of timber should be used around the piers to prevent scour. Ends of piles should be cut off at different levels.

Platform Cylinder Piers.—Platform piers are constructed by driving two or more rows of piles, caps being placed below low water mark. The timbers are laid longitudinally between the piles, and drift-bolted to the piles; and then laying a platform of 6" to 12" timbers transverse and spiked to the caps. The piers are then placed on the platform and securely bolted through holes in the bottom flange angles. Sometimes the piles (Fig. 32), are allowed to project upward through the platform into the piers, thus forming a combined form and Cushing pier. The piers are filled with concrete and similar to the "Cushing piers" previously described. For heavy masonry platform consists of a "grillage" of timbers (say 12"x12") usually in two or more, laid at right angles to the piles. On this grillage the piers are laid.

Concrete Cylinder Piers.—Instead of cylinder piers by the process or on platforms, as previously just described, they are placed on a firm foundation bedded in the material from the bottom, as they descend, and grouting them. If the tubes are sunk in the material may be removed often by using an orange-peel bucket for this purpose. This can be done it will be found economical. But for deep foundation work the pneumatic process is generally used.

Process.—In Fig. 33, *W* is the working chamber, connected with the surface by an air lock. When the workmen or tools go through the lock into or out of the chamber doors *a* and *b* are worked like the doors of an air lock, because the compressed air

pneumatic process is meant the plenum process. The vacuum process is also used.

Fig. 31.

Fig. 32.

Fig. 33.

in *W* is at a higher pressure than the atmospheric pressure. The compressed air, sand and water pumps are on the scow. The material excavated is raised by a windlass. When the air lock has been sunk to water level, a new section of cylinder is inserted and the air lock placed above it. Guide piles may be driven to guide the descending cylinders.

Pneumatic Foundations.—The main essentials for the prosecution of deep foundation work under water, for large bridge piers, are:

- (1) The pneumatic caisson (an inverted, air-tight, "open" caisson), which forms the working chamber, and supports the masonry pier;
- (2) The crib, a cob-like (sometimes solid grillage) construction of timbers above the pneumatic caisson, really forming a part of it, and on which the masonry pier is built;
- (3) The coffer-dam (sometimes omitted), built on top of the crib so that masonry can be laid dry even when below the water level;
- (4) The pneumatic tubes, consisting of air shafts, air locks, etc.;
- (5) The machinery scow, containing boilers, air compressors, engines, and dynamos for lighting;
- (6) The excavating tools, as picks, shovels, windlass for hoisting, etc.
- (7) The sand lift, for forcing out the sand;
- (8) The mud pump, for pumping out the mud.

Fig. 34 illustrates the first four essentials, and Fig. 33 shows the arrangement of main shaft and air lock, enlarged. Note that the air lock occupies (Fig. 34) about a central position in the shaft, high enough to be out of danger from flooding, and low enough to be economical. After the pier is sunk to bedrock the shafts, as well as the working chamber, are filled solid with concrete.

The main essentials will be discussed briefly in detail, as follows:*

The Pneumatic Caisson.—The caisson may be separate from the crib, as shown in Fig. 34, in which case the roof is supported by longitudinal and transverse trusses extending through the working chamber (but not shown in the illustration). But the more modern method is the combined crib and caisson, by which means the crib becomes a part (sometimes the whole) of the truss system, to transfer the central weight, over the chamber, on to the cutting edges of the caisson, during the process of sinking. The combined crib and caisson is typically represented in Fig. 35, which is a general plan and longitudinal section of the coffer-dam and caisson for South Pier of Brooklyn tower foundation of the new East River Bridge (Williamsburg) New York City. Fig. 36 shows a vertical section of same, transverse to bridge axis. Figs. 37 to 40 show details of caisson for North Pier, and Figs. 41 to 43 show details of coffer-dam for either pier.

Fig. 34.—Separate Caisson.

The working chamber (Fig. 35) was 7 ft. high and divided by bulkheads. All seams were calked with two strands of oakum; the chamber was then lined with 3-in. plank, the joints (and spikes to fasten them) being treated as above, and then painted with white lead, making it air-tight. Fig. 40 shows the roof plan of caisson.

The Crib.—Where a crib is used above the caisson proper, it may be a solid grillage, or it may be divided into separate vertical compartments to be filled separately with concrete as the caisson is sunk; or the compartments may be staggered (offset) vertically or open so the concrete filling will form one monolithic mass. The accompanying illustrations (Figs. 36 to 39) show an open crib of the latter type.

* The illustrations of Williamsburg bridge foundations are adapted from the official working drawings.

Fig. 35.—Combined Crib and Caisson.
(See pages 880 and 882.)

The Coffer-Dam.—The coffer-dam as applied to the pneumatic foundation, is really an open caisson (see page 876) resting on top of the crib; or if the crib is omitted, it rests directly on the pneumatic caisson. But sometimes the coffer-dam itself is omitted, as when the masonry is built directly on the crib or on the pneumatic caisson, and its top kept *above high water* as the pier sinks. If this is done, no coffer-dam is needed to shut out the water. But it is not always safe, advisable, or possible (economically) to construct the masonry with the rate of progress corresponding with the sinking of the pier, and hence the coffer-dam is employed. It is usually erected in sections, one above the other. Note in Fig. 35 the substituted bracing against the masonry as the latter is built upward. Figs. 41, 42 and 43 show the bracing in detail.

Section transverseto Bridge Axis

Fig. 36.—Combined Crib and Caisson. (See page 880.)

The Freezing Process.—Soft, flowing mud and quicksand (especially) are the most difficult materials to be encountered in sinking foundations and shafts, excavating for wells, or driving tunnels; and it has naturally occurred to a few inventors to devise means for freezing this material, somewhat beyond the area to be excavated (leaving frozen walls for temporary lateral support), so the actual excavation can be made by ordinary methods, as with the pick and shovel.

Any practical system consists essentially in driving a number of tubes into the ground around the proposed excavation, and a little beyond its outer limits. These are called the "freezing tubes" and may be, say, from 4" to 10" in diameter. They are closed at the lower end and should penetrate the full depth of the soft material. Inside of these tubes are fitted the "circulating pipes," about 1" to 1½" diam., with lower ends open, and extending practically to the bottom of the tubes. The circulating pipes are connected at their tops by a "circulating ring" into which the freezing liquid is pumped; descending through the pipes into the large tubes where by absorbing the heat from the surrounding soil, the latter is frozen; then emerging from the tops of the tubes into the "collector rings" and reservoir. From the reservoir it passes to the refrigerating machine, and then to the pump, thus completing the cycle. Certain modifications of this process have been introduced, but the process in any form is seldom used. The circulating liquid may be a solution of calcium chloride or brine. Ammonia machines have been used with success, with magnesium chloride as the circulating medium.

Fig. 39.—Details of Caisson. (See page 880.)

Plan and Sections of Roof Courses

Fig. 40.—Roof Plan of Caisson. (See page 880.)

— Notes on Details —

TIMBER: All Hor Wall Timbers to be sized on 4 sides; Joints to come at Ver Wall Posts and each Course to break joints with Course above and below Joints to be bolted and each end fastened with a Drift Bolt.

Cross Struts to intersect in same plane, one line being continuous through intersection, the other line being tightly bolted against the first and fished together on top and bottom with 3" x 12" 4 planks, properly spiked.

Joints of Cross Struts to come near intersections and to be halved together 1' long and fished by planks as above.

Hor Joints at base of each section of Cofferd-Dam to be covered by Seam Boards after caulking & sewing with Pitch, also Vert Cor Joints.

Plan of Top of Cofferd-Dam

Fig. 41.—Details of Cofferdam. (See pages 880, 882.)

Fig. 43.—Details of Cofferdam. (See pages 880, 882.)

Masonry Piers.*—In sectional plan, masonry piers are designed largely to accommodate the superimposed loadings. Thus, for swing bridges the center pier would naturally be circular, octagonal, hexagonal or square—the circle being the most economical and the square the least. If the draw is center-bearing, the pier may be of solid masonry; if rim-bearing, it may consist of a circular shell to support the rim or track, and perhaps a central pier or core; the rim and core may be joined by steel struts, or concrete webs, radiating from the latter; or the radiating struts may be used with the central core omitted. But there are other considerations which affect, more or less, the shape of the center pier, namely, the sides of the draw openings for the passage of water craft should be straight, or in continuous line with the up-stream and down-stream arms of the draw rest; where the water way is limited and the stream is swift, the pier should be designed to offer the least resistance to the flow, to ice and to logs; and lastly, for structural reasons, the sectional plan should be simple.

Fig. 44.

Fig. 45.

Fig. 46.

Fig. 47.

Fig. 48.

Fig. 49.

For ordinary river piers supporting the ends of spans, we naturally choose the rectangular section, or one of its modified forms. The modifications are based on such sections as will offer but moderate resistance to the flow of the stream and at the same time economize in masonry. Figs. 44 to 49 show various sectional plans of piers, from the rectangular to the double diamond. The right-hand ends are "up-stream." Note that Fig. 46 shows two types of ends, namely, the semi-circular and the 45° pointed; also that the down-stream ends of Figs. 45, 46 and 47 may be either square, or symmetrical with the up-stream ends. Figs. 48 and 49 illustrate the saving in masonry over Figs. 46 and 45, respectively, by comparing the full

* For masonry *abutments*, see Sec. 25, Masonry, pages 436 and 437.

lines with the dotted (between the ends of the latter); and although not altogether pleasing in appearance they may be (and have been) used as concrete piers in replacing some existing cylinder piers, where the other forms above would have overloaded the pile foundation. Where concrete piers are built hollow, or cobbled (with cross walls), they may generally be reinforced with steel rods.

Summarizing in general, the rectangular type, Fig. 44, is suitable for a land pier; Fig. 46, with semicircular ends, for a land or shore pier; and Fig. 47, with circular arcs (a , b and c being equidistant), for a channel pier in the swiftest current. By combining 47 with 46 (semicircular ends), using the former type below high water and the latter type above, there is obtained a pier at once efficient, economical and graceful (see Fig. 50), and suitable for our deepest rivers and swiftest currents.

Fig. 50.—Practical Type for High, River Piers.

Contents of Piers by Prismoidal Formula.—Where the sides of the piers battered in straight lines the average sectional area multiplied by the total height will give the cubic contents. The average sectional area is

$\frac{1}{6}$ (top area + 4 times middle area + bottom area).

For an ordinary masonry pier of rectangular s-section, Fig. 51, let

length of top of pier, under coping, in ft.;

width of top of pier, under coping, in ft.;

height of pier (between coping and footing), in ft.;

batter of masonry (horizontal + vertical).

Fig. 51.

$$\text{cubic contents in feet} = \frac{h}{6} [wl + 4(w + bh)(l + bh) + (w + 2bh)(l + 2bh)]. \quad (1)$$

$$= h [wl + bh(l + w) + \frac{4}{3}b^2h^2]. \quad (2)$$

the batter is 1 in 24, we have, since $b = \frac{h}{24}$,

$$\text{contents in feet} = h \left[wl + \frac{h(l + w)}{4 \times 6} + \frac{h^2}{6 \times 8 \times 9} \right] \quad (3)$$

$$\text{in yards} = (\text{above, divided by } 3 \times 9) \quad (4)$$

For small piers, the batter is usually 1 in 12, or $\frac{1}{4}$ in 12; for large piers, 1.

(References: Foundations, Sec. 50; Breakwaters, Sec. 52.)

Definitions.—A *wharf* is essentially a platform structure projecting outward from the shore, and alongside of which water-crafts may be moored for the exchange of freight or passengers. The term "quay" is applied distinctly to a wharf which skirts the shore, and runs about parallel with, and extends to no great distance beyond, the shore line. A *pier*, on the other hand, is a wharf which projects outward from the shore a considerable distance; is supported usually on piles or piers; and hence has "open waterways" beneath the platform.

A *Dock* is an artificial receiving basin for water-craft—for loading, unloading, repairing, etc. It need not necessarily be "closed." A common form of dock is the "open" basin between adjacent wharves or piers; thus, we speak of "docking" a vessel, or bringing her up alongside one of the wharves or piers. Where the rise and fall of the tide is excessive and would interfere with loading and unloading, "closed" docks may be used, as those at London and Liverpool. These are provided with gates which are opened only at full tide. It is but a step from the common "closed" dock to the Graving Dock.*

Foundations.—One of the most important features to be considered in the construction of wharves and piers is the foundation. The kind of foundation most advisable to use will depend upon: (1) the uses for which the structure is designed; (2) the nature and character of the soil and foundation bed, and depth of same; (3) the currents, tide limits, and depths of water; (4) the restrictions by the Government, State (and City) as called for by the established—

Pierhead and Bulkhead Lines.—Piers with open waterways may be constructed to the pierhead lines, while wharves of solid construction may be built only to the bulkhead lines. Where two sets of lines exist, one set established by the Government and the other set by the State, the set nearest the shore is supposed to govern. The U. S. Engineers have authority to interpret the true position of established Government harbor lines, and no encroachment is allowed beyond without the approval of the Sec'y of War. Such approval may often be obtained to meet certain exigencies in local conditions.

Construction Methods.—Common methods of *wharf* construction inside of bulkhead lines are: (a) By sinking timber cribs filled with stone, around the sides (inside) of the wharf area, and then filling in behind with earth, perhaps by *dredging* from the outside. (b) By constructing wharf walls of stone or concrete masonry, instead of sinking cribs, and filling in behind them. Care should be taken to have these walls rest on a good sub-foundation or foundation bed, that is, either natural or artificially prepared, as they are really retaining walls of the most treacherous kind: the earth backing is saturated and has a flat angle of repose, and when the wharf is loaded the overturning force may be increased greatly; moreover, the resistance of the wall itself to overturning is decreased considerably when

* A *Graving Dock* (commonly called a *Dry-dock*) is an (excavated) basin into which a vessel can be floated, the gates closed, the water forced out, and the hull exposed for inspection, repairs, cleaning, painting, etc. (See Paper No. 1016, Trans. A. S. C. E., June, 1906, entitled "A New Graving Dock at Nagasaki, Japan.") A *Floating Dock* (commonly called a *Floating Dry-dock*) is what its name implies and need not be defined. (See Paper No. 1042, Trans. A. S. C. E., June, 1907, entitled "The Naval Floating Dock—Its Advantages, Design and Construction," by Leonard M. Cox. Mr. Cox defines the "Marine Railway" and the "Lift Dock" as additional forms of Repair Docks.)

mersed in water. It is a good plan to back such walls with stone spalls or slag, before filling. (c) By any of the methods used in the construction of open piers, which will now be explained.

Piers are usually of timber construction—at least the floors—supported by piling. The latter may be timber-, screw-, disk-, concrete- or cylinder-. *Timber Piles* are most commonly used. They are driven in rows (some of which are frequently driven slanting to give lateral stability), and capped with say 12"x12" timbers thoroughly drift-bolted to piles. The floor may be composed of one or more thicknesses of 3" or 4" planking laid on say 14" stringers resting on the caps and drift-bolted or toe-nailed thereto. A board from 5"x8" to 10"x12" surrounds the edge of the pier. Snubbing piles are driven where required near edge of pier, and allowed to project above the floor level. Fender piles, singly or in cluster, are driven usually at the corners of piers to receive the shock of vessels making landing. The sides of the pier are thoroughly sway-braced with 3"x10" to 4"x12" planking. Where the soil is sandy, *screw piles* or *disk piles* are sometimes employed. A long iron pier at Coney Island is supported on disk piles with disks 24" and 9" thick, the wrought-iron shafts (tubes) being 8½" outside diameter. The piles are calculated to support 5 tons or more per sq. ft. of disk area. They are sunk with the water jet. Where timber piles are subject to the attacks of the *torredo nevalis** (see page 360) the expense of repairs is considerable, hence *concrete piles* and *cylinder piles* are often employed.

Ferry Slips and Bridge Aprons.—A ferry slip is a dock for a ferry boat; a bridge or apron being an adjustable roadway, for rise and fall of tides, raised from the ferry in the slip. Probably the largest ferry boats in the world are those plying between San Francisco and Oakland, Cal. Some of the slips in New York City are designed for boats 250 ft. upward in length. The tremendous force with which these boats sometimes strike the slips in fog, especially during foggy weather, requires the latter to be constructed in the strongest manner compatible with the requisite elasticity, and improvements are constantly being made in their design. Local conditions must be studied for each particular case, as those which fit one locality do not fit another.

The throat or shore end of the slip is usually made to conform closely to the shape of the ferry boat for say ¼ to ½ its length, and from thence tapers outward more or less to the mouth. Sometimes one wing only is added beyond the middle in order to facilitate landing, under certain conditions of wind and tide.

The following illustrations were prepared by the Dept. of Docks and Ferries, New York City, Chas. W. Staniford, Engineer-in-Chief, and were furnished the writer through the courtesy of Mr. S. W. Hoag, Jr., of the Engineering Department.

52.—BREAKWATERS.

General Discussion.—This subject forms one of the most important in River and Harbor Improvements. The term "breakwater" is quite distinct from the so-called "reaction (curved) breakwater," which latter belongs rather under the head of *Jetties* (page 905) and might be termed a "breakwater" jetty or "lee" jetty.

A Breakwater is an arm-like construction projected in the water and designed to form an artificial harbor for sea-going crafts. The foundation is stone, rip-rap, gravel, etc., either deposited loose or sunk in timber cribs. Where the timber cribs are used they are, for permanent construction, projected upward only to within about 2 ft. of low water, thus forming a substructure on which the superstructure is built. The superstructure* is best constructed of stone- or concrete blocks weighing from 1 to 10 or 15 tons; or of concrete deposited *en masse*. If the bottom is soft or silty, a trench should first be dredged on the line of the breakwater, removing all soft material liable to cause trouble by excessive settlement. This method will generally be more satisfactory than the one sometimes employed of using a gravel core in the breakwater and trusting permanent settlement to take place as the breakwater is built up. Although the latter method has proved successful in some instances, there are records of utter failure during the first heavy storm after completion of the work.

For an excellent discussion of breakwater construction, see Paper No. 971, Trans. A. S. C. E., June, 1904, entitled "The Breakwater at Buffalo, N. Y.," by Emile Low. See also Paper No. 15 of Transactions, Vol. IV—Part A, page 324, entitled "The Delaware, Sandy Bay and San Pedro Breakwaters," by C. H. McKinstry. Considerable valuable data on breakwater construction is contained in Vol. VIII—Part 4, Annual Report (1904) of Chief of Engineers, War Department (U. S.). The following illustrations are from these sources:

Fig. 1.—Buffalo (N. Y.) Breakwater.

Types of Breakwaters.—Fig. 1 is a plan of minimum cross-section for replacing the decayed timber superstructure of a portion of the old Buffalo breakwater, with a new superstructure of concrete and stone "shell construction." The maximum cross-section is 32 ft. on the harbor side and 2 ft. on the lake side, making a total width of 78 ft.

Fig. 2.—Sandy Bay (Mass.) Breakwater.

Fig. 2 is a plan of the Sandy Bay (Mass.) breakwater, showing the section adopted in 1902.

* The use of timber cribs projecting above high water is becoming more and more obsolete. But see Fig. 4.

Holyhead....	Rubble mound with superstructure founded above low water.	7860	41.	72	408	59	816	6,425,000	Driveway 40 ft. Path 13 ft. Long sea slope.
Genoa.....	Sorted rubble mound and superstructure, conc. toe.		50.	84	316	M'd 141 Sup'r 49	640		Driveway 40 ft. Path 9 ft. Storehouses in arches of superstructure.
Alderney....	Sorted rubble mound and stone superstructure.	4680	123.	154	480	Mound 62 Sup'r 35	1175	6,345,000	Driveway 30 ft. Path 14 ft. Greatest depth of water and area of cross-section in world, 4200 ft. from shore.
Dover.....	Upright wall stone and conc.		37.	75	60	48	1616		Bottom of chalk firm, was leveled off. 7250 ft. of rubble mound.
Buffalo.....	Rubble mound capped and crib work (conc. capping).	10000	30.	42	150	14	135	1,637,000	
Delaware....	Rubble mound capped with stone.	8040	29.	44	136	20	217	1,746,000	Outer breakwater, on mattress foundation.
San Pedro....	Rubble mound with stone superstructure founded at low water.	8500	48.	62	180	20	285	2,901,000	Under construction. Estimated cost.
Sandy Bay...	Rubble mound with stone superstructure founded below low water.	9200	50.	72	205	20	361	6,828,000	Modeled after Delaware, not completed; cost estimated.

EXCERPTS AND REFERENCES.

The Sea Wall of La Punta, Havana (By W. M. Black. Eng. News, Nov. 14, 1901).—Illustrated: Fig. 1 shows section through steps of sea wall; Fig. 3 shows section of concrete toe with projecting stones to check run of waves. The article gives the composition of the various concretes used.

The Materials for the Concrete of the Buffalo Breakwater (By Emile Low. Eng. News, Sept. 11, 1902).—The gravel and sand were obtained from the bed of the Niagara River by means of a so-called "sand-sucker," described as follows: The vessel consists of a wooden hull 132 ft. long, 30.2 ft. beam and 7.2 ft. depth. The propelling machinery consists of a double non-condensing engine with a steam cylinder 14" dia. and 16" stroke. The boiler is allowed to carry 30 lbs. steam pressure. At the bow is located a centrifugal pump, driven by two direct-connected engines with cylinders 9" dia. and 9" stroke. The suction pipe is 12" dia., and is also a discharge pipe. Located on the deck of the scow is a large wooden box, 85' long, 24' 9" wide and 3' 10" deep, divided into two compartments by wooden bulkheads 4" thick. The capacity of the box is 325 cu. yds. The water charged with gravel and sand is pumped from the river bed (generally 12' deep) and flows into the flume, with screens of $\frac{1}{4}$ " wire spaced $\frac{1}{4}$ " apart in frames 11"x 24". Five tables are given showing various properties of the aggregates, and data regarding the manufactured concrete blocks.

Wave Action in Relation to Engineering Structures (By D.D. Gaillard. Professional Paper No. 31 of the Corps of Engrs., U. S. A.; Eng. News, Feb. 23, 1905).—Paper deals with: Definitions and theory; Height and Length of Waves; Reduction in Height of Waves on Passing into a Closed Harbor; Velocity of Waves; Per Cent of Wave Above Water Level; Depth in which Waves Break; Dynamometer Tests of Wave Force; Comparison of Theoretical Wave Force; etc. Tables and formulas are given.

Reinforced-Concrete Caissons for Breakwaters (By W. V. Judson. Eng. News, July 8, 1909).—Illustrated: plan of caisson and method of computing stresses. Estimated cost of Algoma breakwater, if built of stone-filled wooden cribs, placed on pile foundation and capped with a standard concrete superstructure (the cheapest permanent form) was \$105.18 per lin. ft. Estimate for caisson breakwater was \$103.74. Actual cost of caisson breakwater was \$75.67 + \$2.62 per lin. ft.

53.—JETTIES.

General Discussion.—At the mouths of navigable rivers where there is cross-current, whether the river empties into another or into the sea, sand bars are liable to form, shoaling the water and obstructing navigation. The cost of dredging deep-water channels through these bars and maintaining them is sometimes enormous, hence jetties are often constructed to reduce this annual expense.

Jetties are structures designed to change the shape and velocity of the moving volume of water so that it will do the work, in part at least, of deepening the channel. The volume is contracted laterally and deepened vertically, and the velocity is increased, thereby cutting out the channel and carrying the material further on, some of it out to sea.

"Twin" jetties are formed by two jetty arms converging. One is called the "windward" jetty and the other the "lee" jetty. The windward jetty is placed on the side of the channel on which the sand-drift predominates; the "lee" jetty, on the other side. As twin jetties are very expensive it is customary on large projects to build one jetty first, watch the effect of scouring of channel, shifting of sand bars, etc., and then with this additional data plan the second arm. In selecting the single jetty, sometimes the windward- and sometimes the lee- jetty is chosen. The argument in favor of the latter is that the channel is practically confined from further movement "leeward," as the sand drifts from the "windward" and is swept on or carried away by the current; whereas with the single windward jetty the channel may fluctuate in position instead of remaining permanent and deep. Each particular case requires a special solution.

The "reaction breakwater," so-called, is a single S-shaped jetty designed to increase the scour by creating a centrifugal force to the current, thereby narrowing the volume laterally and increasing the velocity, similar to the natural winding cuttings in river beds. The effect of this type of jetty has not fully been demonstrated, and will be watched with much interest.

Jetty Construction.—Most of the jetties now built are of rock fill, that is, rubble stone dumped from scows or trains. The trains are run out on temporary pile trestles constructed along the line of the jetty. The material is paid for by the yard or ton. Brush and rock are sometimes used but the use of brush has practically given way to rock alone, especially on large work, on account of the action of the teredo and liability to unequal settlement.

Small jetties and bank protections of streams are often constructed by driving two rows of piles, facing them on the inside with planking, bolting and bracing the rows together, and filling the space between with brush and rock. The brush is often tied together in bundles or *fascines* (see Fig. 1). The bottom layer is placed on the bed of the stream transversely to the direction of the jetty, and on these are placed other fascines laying longitudinally between the piles. Between the fascines and the bottom of the side planking,† boxes filled with rock are sunk between the piles; and the balance of the space above, between the planking, is filled with rock, forming a pile crib. This type is often used for the protection of bridge abutments, and frequently as real jetties in deepening the channel.

Fig. 1.—Fascine.

EXCERPTS AND REFERENCES.

The Improvement of the Entrance to Cumberland Sound, Georgia and Florida (By J. H. Bacon. Eng. News, May 12, 1903).—Shows general plans of the jetty-work improvement; table of official record of contract work; and table of sand movement at Cumberland Sound.

Complicated Reinforced-Concrete Jetty-Head, Thames Haven, England (Eng. News, April 22, 1909).—Illustrated.

* The terms "windward" and "lee" relate to the sand drift and not to the direction of the wind, although they are frequently in the same direction.

† The side planking consists of plank spiked or bolted to the inside of piles and laid as far below low water as practicable.

54.—EARTHWORK.*

Uncertain Cost.—In any engineering work the chance of an accurate estimate of the cost diminishes as earthwork becomes the important item; for in the purchase of materials and supplies a fairly correct estimate may be had in advance, but where the labor factor enters largely in a *direct* way great uncertainty exists. Especially is this true where the character of work to be *performed*, as in grubbing, clearing, and "earthwork," is problematical, the quality of labor uncertain, and the rate of wages unstable.

Before making an estimate the engineer should consider: (1) the kind and quality of material to be handled, by digging test pits and by boring; (2) the most approved method of doing the work; (3) the availability of good contractors, superintendents, and foremen; (4) the quality and price of labor. These will be considered in the order mentioned.

Kind and Quality of Material.—No contract should be let or work started before full information as to the character of the material has been obtained. The cost of pits and borings is merely incidental. Not only are they a practical guarantee of the correctness of the estimates but they give timely information necessary for the purchase and proper disposition on the work of the necessary tools and machinery. The writer has seen steam shovels delivered where nothing short of dynamite could be used, and the expense of such changes and incidental delays is enormous. For trench work, test pits will generally determine in advance whether shoring plank will be required, so they can be ordered in time. One of the first things to look for is the material "hard-pan," "cemented gravel" or "glacial drift," as it is variously termed. When not classified it is a source of contention. Lying beneath the soil, unseen, it is often from 3 to 5 times as expensive to remove as is the material above, especially in trench work where it cannot be loosened economically or handled with the steam shovel. It comes between the earth and the loose rock or the sand-rock classifications and should be mentioned in specifications. Stiff clay is sometimes as hard to work as many of the hard-pans, and some idea should be had of the proportionate amount of this material. If it is large the estimate of cost of "earth" should be raised accordingly. Loam is about the easiest material to shovel by hand, while sand and gravel are more difficult. Loose and solid rock are considered under the next subject heading (Section 55). Sandrock is a partially formed sandstone. It may be in various degrees of hardness, and should receive a separate classification.

Approved Methods of Handling.—Space will permit only of the briefest mention of the methods employed, simply to recall them to the attention of the reader.

Clearing and Grubbing.—After the trees are cut down the stumps are usually blown out with giant powder (No. 2). An effective method, however, which is sometimes employed, is to snatch them out with a donkey engine. This has been done economically on railway right-of-way in the State of Washington, where the stumpage is thick. Quite a common method is to twist them out by using horses at the end of a horizontal lever chained rigidly to the stump; but only small stumps can be removed in this manner. The method of burning stumps is a slow process and not generally resorted to on engineering work. It takes many years for stumps to rot. The brush-hook is very serviceable in cutting brush, especially small willows and alders. Grubbing the roots of trees is best accomplished with the grubbing-hoe or mattock. Strange to say, estimates for clearing and grubbing are almost universally too low. The price is usually *per acre*, or sometimes *per station* on railroad work. In reservoir work for domestic water supply the grubbing must be done most carefully in order that the top soil may be removed unobstructed. Under railroad fills the

* For earthwork Tables, see Sec. 59, Railroads, page 1017, etc.

often left standing, unless the depth of fill is small. For trench or pipe-laying, it is best that the grubbing and excavation con- together—to the same party.

ing Earth.—The team with driver, and plow with holder, are the omical outfit generally; but four or six horses, with two men at re often used on railroad work especially if the material is hard. bial "six-mule-team" requirement often denotes the upper limit a earth classification. Hard-pan may be plowed generally with tfit but *not always economically* and it may be cheaper to use arse, black). For narrow trench work and for shallow bank ex- such material, the common pick is used.

g and Conveying.—For widening and deepening large railroad eam shovel stands pre-eminent. The size of the shovel (capacity dipper, or scoop) should be gaged to the depth of cut or rather t of material which can be loaded on the cars from one position, g up" is expensive. A shallow cut would call for a pony shovel, shallow, hand shoveling might be cheaper. A cu.-yd. bucket is a or an average cut. In considering the use of any (steam) plant t on cost, the depreciation, the operating expenses, and the t be proportioned to the total yardage, hence the greater the e more expensive may be the outfit, provided of course that it tly economical while in operation. Errors are often made in o complete a plant for the work; and also in the other direction. ial is usually loaded in trains of self-dumping cars operated by . If the delivery track to the steam shovel is on a proper grade, 2%, the cars may be operated by gravity in making-up the ns. If flat cars are used they may be unloaded cheaply with a n the full length of train.

ng out long sand cuts, where the material can be hand shoveled osening, a good outfit consists of small dump-cars (side-dumping) a train on a narrow gage track. There is usually more or less of ade from cut to fill, and this gravity power may be assisted by h draw the empty cars back.

heeled carts with removable slat bottoms, and two-wheeled are used in excavating cellars where the material is removed from t they have practically been crowded out by the wheel and drag ordinary railroad grading. The drag scraper is specially efficient tting from cuts and for short leads generally; the wheel scraper, for s. The Fresno scraper is popular in the West and is considered most efficient scrapers on the market. Wheelbarrows are used muddy places.

ous conveyor systems have been employed for side-waste from cuttings. The plane rubber belt and the movable-bucket types et demonstrated their practicability. The combined hoist and are generally employed in deep sewer excavations, large buckets

Steel cableways are sometimes used in mining and river-bottom for dams and foundations.

Fig. 1.

avation of the Chicago Drainage Canal developed types of the ane and movable bridge conveyors unique in their magnitude, simply steel structures for conveying loaded cars from the canal over the spoil banks for dumping. The first named was a canti-second a simple span, placed transversely to the canal and resting arallel with the canal (see Fig. 1).

arson trenching machine is of this type. See "Cable Hoist- for general use on large work; published by The Trenton Iron

There are many graders, trench machines and excavators on the market, many of which are greatly overrated in efficiency and capacity. Some of them work well in loose soils but are useless in the harder materials liable to be encountered. Caution should be exercised in their selection.

Under favorable conditions where there is plenty of water, excavation and fill by hydraulic method is sometimes the cheapest. The favorable conditions are a gravity supply of water obtained with little expense, the right kind of material as sand or fine gravel, sufficient grade from cut to fill, and a short conveying distance. The material is washed from the natural bank by concentrating a stream from a nozzle, or giant, and is carried in a sluice box under a constant stream of running water. The required grade of the sluice may be as great as 8 or 10 per cent for very coarse material. Earth dams constructed in this manner are plentiful in California. Part of the water front at Tacoma, Wash., has been filled by washing down the steep bank and sluicing the material into the bay. If there is no gravity supply and pumping is required the chances of the hydraulic method being the cheapest are greatly lessened.

One other method which may be touched upon in this connection is by hydraulic dredging. By the use of a rotary cutter and a suction pump the fine material from the bottom is sucked up and forced into a sheet-iron pipe leading to the shore. Filling operations along our water fronts bear witness to the efficiency of this method. Material is frequently delivered one-half mile from the dredge, and sometimes to a much greater distance.

Superintendence.—Some years ago a certain engineer known to the writer entered into a term contract as Chief Engineer with a contracting firm at a stated salary and a certain percentage of the profits. One of the first contracts secured was for the construction of headworks and a 30-mile pipe line for water works in one of our prominent western cities. The amount of the contract was over \$900,000.00. The estimate was based on prevailing prices, the prices for material being guaranteed in most cases. A profit of 25% was added to all estimated costs, including materials furnished. The Treasurer* volunteered to go up and superintend the work, as it would be a nice outing for him. They had other contracts on hand but this was the largest, and the profit on the steel pipe material alone, delivered, was about \$50,000.00. The wood-stave pipe construction was under an experienced man. The Treasurer was a fair book-keeper. When the work was about half completed the City Engineer became desperate and called at the main office. "Fully a hundred thousand dollars had been wasted on the line. Men all over the line working without sufficient tools; one gang of 12 with only one shovel between them, and no pick. Material from the trench being wasted improperly, that had to be used again for back-fill." Upon investigation it was found that these were facts; that the office force was up to its ears in book-keeping; that there was no active superintendent or line boss; that not one of the foremen had been furnished with a profile of the line or had been instructed where to make his spoil banks; and after the pipe had been laid, extra borrow pits had to be opened for back-fill! It proved to be an expensive "outing," and the loss fell most heavily upon the Treasurer himself who was the principal owner. Here is a case where a good superintendent could have saved the company ten times his salary.

Good foremen keep track of how much each man is doing, know what he ought to do, and whether he is doing a day's work. It is a mistake to drive men who are resting occasionally, as the one who "keeps moving" may not be doing half as much work. Poor foremen can wipe out the profits in a contract even although they may appear to be "hustlers."

Labor.—The common labor problem is a difficult one to solve. Generally, "white" labor is the most profitable but it is hard to secure, exclusively, on large work. Italian and Chinese come next in order. A method commonly employed with some contractors is to select one or two good men in each gang, secretly pay them from 25 to 50 cents more per day and let them "set the pace." As a further incentive a small bonus is sometimes offered to the other men if a certain amount of work is accomplished. In

* There was considerable rivalry between the Treasurer and the Secretary as to who should "boss" the job, which was acknowledged to have been the best one ever landed on the Pacific Coast up to that time.

the cost of earthwork the labor cost is the main item. It may be as a fixed rule that, with the same class of men the cost of labor increases more rapidly than the increase in wage, because under any conditions demanded by "good times" the men will actually do less work; they will not work as steadily; and there will be more trouble in the working force, preventing thorough organization. Thus, if the work cost A dollars with labor at \$1 per day, it might cost 2A dollars with the same labor at \$1.75 per day, the extra cost, $\frac{1}{2}A$, being added to reduce materially the contractor's profit. Hence, estimates based on labor costs should be used with caution.

Embankment.—Dry earth embankment for railroad and other works is universally carried up with slope of $1\frac{1}{2}$ horizontal to 1 vertical. Dams and reservoir embankments, much flatter, as 2 to 1, $2\frac{1}{2}$ to 1, etc. The latter are built in horizontal layers and usually rolled, while the former are built largely by side and end dumping. To illustrate the best reservoir embankments are composed of fine gravel or sand and a clay to form a good binder, being *puddled* by sheep or cattle over it during construction, and sprinkled with a moderate amount of water. "Spike" rollers are an imitation of the above. Grooved rollers are better than plane rollers.

Shrinkage of Earth.—Earth in place swells when loosened, but under the influence of pressure and moisture it tends to recede to its original volume. In some cases, to lesser volume than it previously occupied. The phenomenon is illustrated in laying water pipe: A trench is dug, pipe is laid, and back-filling is done with thorough wetting and tamping. Often, the pipe is to be borrowed to fill the trench, notwithstanding that the pipe occupies but a small portion of it.

The subject of shrinkage has received much attention from various engineers and has provoked considerable discussion, especially during the past few years. The variance in the different conclusions drawn is of course mainly to the lack of definite and careful experiments and exact data, and partly to incorrect analysis. The special problems connected with railway embankments are:

1. That quantities in "cut" (unmeasured) shall be assumed to be equivalent to the volume of the material after being placed in "fill" (and measured therein for final estimate)?

2. That shall be the tentative cross-section of a fill so that when practically final settlement has obtained, the lines of the fill or embankment shall be those of another cross-section, predetermined? In discussing these questions a great many factors have to be considered, and the following are the principal ones:

Are Earths? Earths are mainly metallic oxides which are practically insoluble in water, as alumina, glucina, yttria, thorina, etc.—the silicates, as baryta, lime, magnesia, strontia, etc., being somewhat soluble in water. Chemically speaking, earths are dry, inodorous, uncombustible substances, fusible only at extremely high temperatures.

Are Soils? Soils are earths, composed of the broken and weathered fragments of the earth's crust, mixed with varying proportions of organic matter, and are, either decomposed or in a state of decomposition. Sedentary soils are those soils which rest upon the parent rock from which they were derived. Transported soils are those soils which have been removed and deposited elsewhere by the action of water, glaciers, or wind; if by wind, they are usually termed Aeolian soils.

The density of Soil in its natural bed depends upon its composition, the nature and method of deposition; also upon the action of the vegetable life in the soil, in connection with the action of the percolating water, of frost. Thus, heavy soils, as hard clay and cemented gravel, under the action of water or glacial action, under pressure, will be very dense; while light soils, as volcanic ash, deposited dry by the wind, will naturally be very light. But these light soils may become dense through the action of glacial action above described; while the heavy surface soils, so long as they remain in turn become light and porous through the action of the water—dissolving certain of the chemical elements and giving them off in plants or carrying them away, or carrying away (perhaps into the sea) the small (or even large) suspended particles themselves;

and the voids thus created being further increased by the action of frost, tending to swell the soil. Hence it is seen that soils may have different densities, even if of the same composition, when lying in their natural beds.

The Effect of Water on excavated soils is to settle them, mechanically, and to make them more compact; with the notable exception of clay, which swells when moistened and shrinks again when dried. Thus, with most soils the water will deposit the finely suspended particles of matter into the voids of the coarser material, decrease the friction, and settle it into a denser mass; while with clay the admixture of water produces a colloidal state, causing the mass to expand.

The Effect of Temperature on soil- or earth embankment is mainly the effect of drying out the water, or of producing frost action; the direct expansion or contraction due to temperature, being extremely slight, and negligible.

The Effect of Vertical Compression or Jarring on an earth embankment, is a downward tendency to settlement and a lateral tendency to expansion. This statement as to lateral expansion does not of course take into consideration any side-surface slides of the mass, or wash of slopes from rain.

The Effect of Stirring or Puddling is to make the soil or earth denser by decreasing the percentage of voids. The following experiment was made with coarse sand, which had all passed through a $\frac{1}{4}$ -in. sieve (16 meshes to the inch): A box of one cu. ft. capacity was filled with the sand, then jarred to settle it, and again filled to the top. Water was then poured in, filling all the voids in the sand, the amount of water used being 0.342 cu. ft., thus measuring the voids in the sand as 34.2%. The wet sand was then thoroughly stirred, and settled in the box to 82.5% of its original volume, the voids in the stirred sand being therefore 20.2% of the final volume.

In the following discussion the term earth will be considered to include soil.

Swellage (*w*) of Earth takes place, usually, when it is first dug. This is due to the loosening of the material, thus increasing the voids. The more thoroughly it is loosened the greater will be the swellage. But it can immediately be Compressed or compacted to its original volume, or be made to Shrink below its original volume, if water and sufficient pressure are applied. The Percentage of Swellage is the percentage of increase in volume of the loose material excavated, based on the original volume of the material in situ.

Compression (*k*) of Earth takes place, more or less, in forming any embankment; that is, the loose material is compacted somewhat, even by its own weight, while being placed. A low embankment formed by shovel work, or by dumping from a cableway, or from a train supported on a trestle, especially during dry weather, would naturally show little compression during the short period of time required in its construction; while the material forming a high embankment might be compressed appreciably under the same conditions of construction, owing to the increased weight of the bank and the element of time, both of which are important factors. If the track were supported directly on the embankment itself, or the material delivered in wheelbarrows, or especially if carts or scrapers were used, the compression would be increased; while if the material were spread in thin layers and rolled with a heavy roller, the compression would be much greater. The Percentage of Compression is the percentage of reduction of volume in placing the material in the embankment, based on the volume of the loose material after being excavated.

Contraction (*c*) of Earth in embankment continues, perhaps, indefinitely; but the rate of contraction, under constant conditions, decreases with time. That is to say, under the same conditions the rate of contraction decreases as the material in the embankment becomes more dense. The rate of contraction, however, may be increased by pressure, by jarring or shaking and usually by moisture or sprinkling. Thus we have as factors tending to contract the material in the embankment: The pressure of the embankment itself, the pressure and jarring due to moving trains, and the sprinkling due to rainfall; added to this, is the wash of the slopes which, for our immediate purpose, will be included under the present heading. The Percentage of Contraction in Embankment is the percentage of decrease in volume at any stated time after the work is completed, based on the volume of the compacted materials as placed in embankment.

Shrinkage (*s*) of Earth is also measured in per cent, and is the ratio of the loss in volume of earth (measured) in embankment at any specified time.

the original volume which the same material occupied before being excavated (that is, in situ).

Shrinkage may be obtained approximately by the following formula:

Notation (from preceding discussion):

Swelling % = ratio of increase in volume of loose material excavated, to volume of same material before being excavated;

Shrinkage % = ratio of decrease in volume of placed material in embankment, to volume of same material loose after being excavated;

Settlement % = ratio of decrease in volume of material in embankment at any specified time, to volume of same material when placed in embankment;

Shrinkage % = ratio of decrease in volume of material in embankment at any specified time, to volume of same material before being excavated.

Formulas:

$$\text{Shrinkage } s = 1 - (1 + w)(1 - k)(1 - c) \dots \dots \dots (1)$$

measured immediately embankment is completed,

$$s = 1 - (1 + w)(1 - k) \dots \dots \dots (2)$$

Wrong conclusions arise in current discussions on shrinkage of earth partly from the erroneous assumption of some writers that the shrinkage is based on the volume of earth in embankment or fill, instead of the original volume in excavation.

Tables 1, 2 and 3, following, give the approximate values of $(1 + w)$, $(1 - k)$ and s , in Formula (1). They are intended merely as a covering average and extreme ranges, and in no way absolute, as is apparent from the greatly varying conditions of construction previously discussed.

ments on the Shrinkage of Earth are scattered, and most of them satisfactory because the data are not complete. In all experiments the prismoidal formula should be used in the calculations, errors amounting to from 3 to 10 per cent would be quite usual in and enough to destroy the value of the results obtained. It becomes necessary to base an estimate on the quantity in embankment as the contract price was based on the quantity in excavation, as should be made on the shrinkage of the material.† The usual method of making these experiments is to dig a rectangular-shaped pit, or trench, and then place the excavated material back in the pit or trench in conditions similar to those in making the embankment. The shrinkage will then be the difference between the original volume of the material and the final volume of the placed material, divided by the original volume of the pit.

Morris, about two-thirds of a century ago, made some measurements on a large scale, on the shrinkage of earth. The embankments were made by carts and scrapers, and one winter intervened between

the measurements. The s are actual shrinkage averages from original volume in excavation. Where the minus sign appears before these values, it indicates an increase in volume by that amount.

Contracts on railroad work stipulate that when material is used in an embankment a certain percentage, say 10%, shall be added to the original volume.

the commencement and completion of the work." The results of the measurements, involving nearly 44,000 cubic yards, are: Shrinkage of yellow clayey soil, 9.25 to 10.15 per cent; shrinkage of light sandy soil, 12.93 per cent; mean average shrinkage, 10.3 per cent. Based on these experiments some authors give the "shrinkage of earth" as 9 to 13 per cent, while others have widened the range to 8 to 15 per cent. Most railroads use about 10 per cent as an average working basis.

The Am. Ry. Eng. & M. of W. Assn. Committee Report for 1907 recommends shrinkage allowance for both height and width in new banks, 20 replies favoring this, while two favored allowance for vertical shrinkage only, and two for horizontal shrinkage only. The following shrinkage values were recommended:

	Suggested by Members.	Recommended by Committee.
Black dirt, trestle filling.....	7 to 30%	15%
Black dirt, raising under traffic.....	4 to 20%	5%
Clay, trestle filling.....	5 to 30%	10%
Clay, raising under traffic.....	2 to 20%	5%
Sand, trestle filling.....	3 to 15%	6%
Sand, raising under traffic.....	2 to 15%	5%

In building the Tabeaud Dam, 1900-1902, near Jackson, Cal., tests of the earth material used showed the following average weights per cu. ft.:

Dust dry soil (angle of repose 36°)..... 84.0 lbs.
 Soil fully saturated, 52% moisture (angle of repose 28°)..... 101.7 lbs.
 Natural bank soil, 19% moisture (angle of repose 44°)..... 116.5 lbs.
 Delivered from wagons, moist and loose (showing swellage of 52%) 76.6 lbs.
 Loose dirt from dam, shaken down and measure struck (swellage 45.6%)..... 80.0 lbs.
 Material in dam, 38% gravel and grit, thoroughly sprinkled and rolled (showing shrinkage of 12.4%)..... 133.0 lbs.

Experiments made by Mr. D. C. Henny, on earth material for the Cold Springs Dam, Umatilla Irrigation Project, Oregon, show the following results:

* Sample.	Specific Gravity.		Percentage Voids.			Uniformity Coefficient.	Effective Size—mm.	
	Constit- uents.	Mass.	Dry.		Wet Rammed.			
			Loose.	Compact.				
A. Surface soil.	2.52	1.41	59	49	44	3.9	.023	
B. Fine subsoil.	2.65	1.55	54	43	45	4.0	.025

20%	80%	2.91	2.04	47	40	30	76.7	.091
15%	85%	2.84	1.88	41	35	34	18.0	.163

* Sample A is the 12-in. surface soil in the bottom lands, being darker in color than the deeper-lying soil, but containing a sensibly greater quantity of organic matter, as roots and vegetable fibers. Sample B is taken from 1 to 4 ft. below the surface, being slightly lighter in color than A, and with less vegetable matter. Sample C is coarse sand gravel and from the steep side-hill, the mass of the material being a coarse sand or fine gravel with a considerable proportion of gravel that would be retained on a one-inch mesh; also occasional large cobbles, and a scantiness of fine sand. Sample D is volcanic ash, almost pure white in color; when in place it appears to be slightly indurated. Sample E is a coarse soil, coarser in appearance than A and B but otherwise greatly resembling them; it lies from 1 to 4 ft. below the surface. Samples A, B and E all contain a considerable proportion of volcanic ash and vegetable matter, and are fairly representative of soils in that section of the West. †Massachusetts State Board of Health standard.

Experiments made by Mr. Emery Sudler, on soils for use in construction of earth dam for water-works reservoir, Baltimore, Md., show the following results:

Properties or Condition of Material.		Yellow to Brown Clay, from layer 2-ft. to 4-ft. thick.	Soft, rotten Serpentine Rock, below the clay.
Weight in lbs. per cubic foot when moist.....	In place.....	116.	108.
	Loose.....	78.	74.5
	Compressed (in 4-in. layer in 6-in. test pipe, at about 150 lbs. per sq. in.).....	131.6	129.3
Volume in cubic feet corresponding to one cubic foot in place..	Loose.....	1.5	1.45
	Compressed.....	.86	.84
Absorption by weight.....		.007	.007

This table shows that when loosened the clay swelled 50% and the rotten rock swelled 45%; after being compressed the loose clay showed a compression of 40.7% and the loose rotten rock a compression of 42.4%; while the ultimate shrinkage of the material in place when compressed, was: clay, 11.9% and rotten rock, 16.5%.

Shrinkage in Volume = Vertical Shrinkage.—If each particle in an earth embankment shrinks vertically (not laterally) how will the settlement of the top of an embankment compare with the shrinkage in volume?

Fig. 2.

Solution.—Let the full lines, Fig. 2, represent the original fill, and the dotted lines the top and slopes after vertical shrinkage. Then will $d+h$ represent the ratio of vertical shrinkage, as well as shrinkage in volume. For

$$\frac{\text{Final volume}}{\text{Original volume}} = (h-d) \frac{(b+t)}{2} + h \frac{(b+t)}{2} = \frac{h-d}{h} = 1 - \frac{d}{h}.$$

Earthwork is always measured in excavation where possible; but it often happens that a contractor will start in on a borrow-pit before it is cross-sectioned. For this and other reasons it is sometimes necessary or advisable to measure up the embankments as a basis for payment. Considerable judgment must therefore be exercised in the question of "shrinkage."

Performance of Work.—The following items are selected and digested from the columns of *Engineering-Contracting*,* and give what may be considered fair averages of good work under the conditions named. For detailed information see original articles. References are made to the files of *Eng'r-Contr.* in the following manner; thus, E.-C., (date, page).

Sewer Trench in stiff clay, wet and soft in spots, but tough digging; at West Allis (near Milwaukee), Wis.; by "Buckeye Traction Ditcher," a machine with buckets on the periphery of a large wheel, operated by steam, costing about \$4600.00, and manufactured by the Van Buren, Heck & Marvin Co., of Findlay, O. Estimated performance (less than actual) 900 lin. ft. of trench 2 ft. wide by 7 ft. deep in 10 hrs. at cost of 5 cts. per cu. yd., including all items of pay roll, fuel, interest and depreciation.—E.-C., Jan., 1906, p. 7.

New York Subway. Earth excavation in a typical section of about $\frac{1}{2}$ mls. Brooklyn Extension: Excavation proper (labor 1.60, materials and plant 0.32, power 0.02, dump charges at 60 cts. per load 0.25), \$2.19 per cu. yd.; bracing and sheeting (labor 0.78, materials and plant 0.37), \$1.15 per cu. yd.; pumping and draining (labor 0.01, materials and plant 0.01, power 0.01), \$0.03 per cu. yd.; bridges and barricades (labor 0.10, materials and plant 0.14), \$0.24 per cu. yd.; backfilling (labor), \$0.01 per cu. yd. Grand total, \$3.63 per cu. yd.—E.-C., Feb. 1906, p. 30.

Panama Canal. Cost per cu. yd. of mixed excavation (96052 c. y. hard rock, 254252 c. y. soft rock, 391340 c. y. earth), for a total of 741644 cu. yds., between July 1, 1904, and June 30, 1905: July, 65.4 c., Aug., 50.6 c., Sept., 57.3 c., Oct. 54.1 c., Nov. 50.1 c., Dec. 52.8 c., Jan. 47.8 c., Feb. 46.5 c., Mar. 43.3 c., Apr. 52.5 c., May 83.8 c., June 102.7 c. Excavators and steam shovels were used. Roughly, the above costs include up-keep, depreciation, etc., of plant.—E.-C., Feb., 1906, p. 44.

Intercepting Sewers, Chicago. (1) Excavating with Ennis type derrick, equipped with a 1 cu. yd. Haywood orange-peel bucket, an 8 $\frac{1}{2}$ " by 10" double-drum hoisting engine and 60-ft. boom. Cost, exclusive of wear and tear of machinery, 6.6 cts per cu. yd. (2) Other methods were used also.—E.-C., Apr., 1906, p. 96.

R. R. Excavation with Elevating Grader. 7 examples, by D. J. Hauer. Material, average earth when dry. Machine built by the Nat'l Drill and Mfg. Co. of New York City. Wagons, drop bottom patent dump, of 2-yds. capacity. (1) R. R. cut, 400 ft. long, 45 ft. wide on top. Cost (loading 0.130, handling 0.111, dumping 0.041, water boy 0.001, foreman 0.012), 29.5 cts. per cu. yd. Av. output, 206 cu. yds. per day; lead, 400 ft. (2) R. R. cut about 1400 ft. long, 20 ft. wide and 2 ft. deep. Cost (loading 0.067, handling 0.078, dumping 0.011, water boy 0.002, foreman 0.007), 16.5 cts per cu. yd. Av. capacity, 380 cu. yds. per day; lead 1000 ft. (3) R. R. cut, 30 ft. roadbed for double track. Cost (load. 0.046, haul. 0.072, dump. 0.016, water 0.001, foreman 0.005), 14 cts. per cu. yd. Max. output at top of cut, 510 cu. yds. per day; av. output, 300 cu. yds.; lead 600 ft. (4) R. R. cut for double track. Cost (load. 0.108, haul. 0.149, dump. 0.019, water 0.003, foreman 0.010), 28.9 cts. per cu. yd. Av. output, 284 cu. yds. per day; lead, 700 ft. (5) R. R. cut. Cost (l. 0.061, h. 0.077, d. 0.018, w. 0.002, f. 0.006), 16.4 cts. per cu. yd. Av. output, 417 cu. yds. per day; lead, 500 ft. (6) R. R. borrow-pit. Cost (l. 0.098, h. 0.094, d. 0.049, w. 0.003, f. 0.009), 25.3 cts. per cu. yd. Av. output, 260 cu. yds. per day; could have been increased if more wagons had been used. Lead, 500 ft. (7) R. R. borrow-pit. Cost (l. 0.153, h. 0.260, d. 0.050, w. 0.002, f. 0.015), 48 cts per cu. yd. Av. output, 167 cu. yds. per day; material hauled 1700 ft.; management inferior.—E.-C., Apr., 1906, p. 102.

Steam Shovel Work on Ann Arbor R. R. in 1895. Cost figures cover loading, hauling and placing under track, but make no allowance for rental of plant, locomotive or cars, nor for depreciation of plant. Labor, \$1.15. Cost per cu. yd.: Sand, 7.22 to 13.88 cts.; sand (very light face), 17.24 cts.; sand (all work lowering by hand charged against this cut), 25.44 cts.; sand (light face), 13.25 cts.; quicksand, 13.98 and 15.95 cts.; gravel, 8.93 and 14.37 cts.; gravel (long haul), 19.81 cts.; clay, 9.60 to 14.01 cts.; clay (hard pan), 17.65 cts.; sand and gravel, 6.48 and 8.58 cts.; sand and gravel (very light face), 17.31 cts.; sand and clay, 10.49 cts.—E.-C., May 30, 1906, p. 151.

Sewer Tunnel at Cleveland, Using Hydraulic Shield. Sewer, 13 $\frac{1}{2}$ ft. dia., built of four rings of No. 1 shale brick laid in Portland cem. mortar. Shield, 16 $\frac{1}{2}$ ft. dia., 4 ft. long, of $\frac{1}{2}$ " metal, and weight about 16 tons; upper half provided with follower 7 ft. long, of $\frac{1}{2}$ " steel, bolted to shield. Shield pushed forward by 12 hydraulic jacks, 5" dia. and 26" long. Water led to jacks by pipes with swinging joint; av. pressure about 700 lbs. per sq. in., but pump could develop 6000 lbs. Material, hard, dry quicksand, sometimes mixed with clay. Cost of tunnel per lin. ft.: 8 c. y. excav., underground labor, at 73 cts.—\$5.44; 8 c. y. excav., surface labor, at 48 cts.—\$3.82, 2.62 c. y. brickwork, underground labor, at \$1.22—\$2.95; 2.62 c. y. brickwork, surface labor, at 73 cts.—\$1.91; 1100 bricks @ \$9 per M—\$9.90; 2.1 bbis. cement (1:3 mortar), at \$1.70—\$3.57; 1 c. y. sand at \$1—\$1.00; plant, 50% of first cost, distributed over 1625 lin. ft.—\$5.00; lumber—\$1.05; shafts or manholes—\$1.00. Total \$35.64.—E.-C., July 25, 1906, p. 22.

Clearing and Grubbing Land; and Blasting Stumps. Area, 9 acres; trees, 6 ins. to 3 ft. in dia., with average about 20 ins., consisting of oak, hickory, chestnut, etc.; number of trees cut was over 1100, and number of stumps blasted was 1212. Trees under 6" dia. classed as brush, and stumps were grubbed with mattocks. For blasting stumps the following were used: 1 churn drill, 1 large auger, and 1 bucket, costing in all about \$80. Total cost per acre was as follows, with Italian labor at \$1.25: Chopping \$18.84, grubbing and clearing \$15.53, making cord wood \$10.14, blasting \$73.73, grubbing after blasting \$35.26, grinding axes \$0.65, tools \$9.00; total cost per acre \$163.25.—E.-C., Feb. 27, 1907, p. 98.

Wash Drill Borings, Deep Waterways Survey, Great Lakes to Atlantic Tide Waters, 1897-1900. The process consisted in alternately "driving casing" and "drilling" until "bottom" was reached. Where obstructions were encountered that could not be passed by drilling, they were removed by pulling the drill rod and lifting the casing 3 or 4 ft. and then firing a stick or two of dynamite at the bottom of the hole. (a) On the Tonawanda-Olcott and La Salle-Lewiston Routes, compris-

ing 404 holes bored to an aggregate depth of 9624 ft. The cost of borings (including total cost of plant) was 68.63 cts. per lin. ft., the material being sand, gravel, clay, and hardpan. (b) On the Western Division of the Oswego-Mohawk Route—from Oswego to Rome—750 holes were bored to an aggregate depth of 33711 ft., and at an average cost of 70.07 cts. per lin. ft. For the Oswego river and harbor work, the machines were mounted on small flatboats with open wells at the center; and the work on Oneida Lake was done through the ice. (c) On the Eastern Division of the Oswego-Mohawk Route there were made 290 soundings by hand with a steel rod, and 1562 actual borings, together amounting to 55521 ft., aggregate depth, at a cost of 54.19 cts. per lin. ft. The borings varied from a few feet to 190 ft. in depth. Four types of machines were used, viz.: 1 Pierce well-boring machine, 1 Sullivan wash drill, and 2 home-made affairs. The material encountered was, sand, 20706 ft.; clay, 9680 ft.; earth, 7611 ft.; sand and clay, 3176 ft.; gravel, 2815 ft.; sand and gravel, 2728 ft.; sand, clay and gravel, 1843 ft.; quicksand, 1529 ft.; clay and shale, 903 ft.; sand, loam and mud, 900 ft.; clay and gravel, 760 ft.; rock, 626 ft.; mud, 417 ft.; miscellaneous, 1628 ft. (d) On the Champlain Route from Ogdensburg to Lake St. Francis there were 148 sand borings totaling 7052 ft., and 151 water borings totaling 2123 ft. The cost of the 9175 ft. of borings was 84.18 cts. per lin. ft. (e) On the Hudson River Division of the Champlain Route 57991 lin. ft. of borings cost 12.35 cts. per lin. ft. (f) On the Hudson River Survey, Hudson to Troy, the borings were made with an outfit mounted on a catamaran and on scows. Silt, clay, coarse and fine sand, gravel, and boulders were penetrated. A 2½-in. casing and "B drill rods," with X-bits were used. In all, 1385 borings were made aggregating 28965 ft. in depth and costing 25.07 cts. per lin. ft.—E.-C., Mar. 27, 1907, p. 132.

Trenching and Backfilling for Pipe Sewer, Centerville, Iowa. Data from which the above was compiled was furnished by Mr. M. A. Hall, engineer in charge, from daily reports by inspectors, and Mr. Hall suggests adding 10% for possible omissions in

labor roll. There were 53 Jobs in all, and these are numbered by "side and top" method. The following information is p = dia. of pipe, in ins.; t = size of trench, width by depth; d = yard for digging trench, b = cost in cents per cubic yard for 18 cts. per hour.

[Add 10% to d: = cost (cents) per cu. yd. for digging; b = same for back-filling.]

hydraulic Fill Dams. (1) Croton dam on the Muskegon River, Mich.; a feet below the junction of the Big and Little Muskegon. Sluiced embankment 50 ft. long, 55 ft. high and 20 ft. wide on top; containing 104000 cu. yds. of gravel. Maximum distance sluiced, 800 ft.; grades generally 8 to 10 ft. of finished embankment, 2 to 1 and 3 to 1. Two Ramsey and two rotary fire pumps were used, operated by electric power. Total cost of construction, including superintendence ($\frac{1}{2}$ cent), 7.3 cents per cu. yd. (2) Lyons dam, on the valley. Embankment 150 ft. long and containing 23000 cu. yds. of gravel was sluiced into place. Total cost including plant minus salvage, including superintendence (3 cents), 36.01 cts. per cu. yd. The high cost was due to the expense of carrying the troughs, and from trouble with ice.—*E.-C.*, Nov. 13, 1907.

Steam Shovel Excavation. (1) Earth. Excavation by steam shovel and transportation 19.42 cts., tracks 8.30 cts., dumps 15.48 cts., general expenses, arbitrary to cover cost of plant 12.00 cts.; grant total 67.94 cts. per cu. yd. (2) Rock. Add 25.57 cts. to above for blasting, making grand total of 93.51 cts. per cu. yd. (3) Dredging. Cost of dredging 1,213,597 cu. yds. of soft material, by one dredge was about 10 $\frac{1}{2}$ cts. per cu. yd.—*E.-C.*, p. 32.

Work Classification.—The object of classification is to fix a basis for determining the cost of work by unit prices which will be fair for any material encountered and for any reasonable changes in the original estimate. Of all, the engineer who draws up the specifications should keep in mind the kinds of material he is classifying, not merely by name, which is often misleading, but by a thorough practical knowledge demonstrated to intending bidders. The writer, as contracting engineer, has been on work where test pits were dug showing material which the engineer who drew up the specifications could not classify himself. An impression received, however, was that it would be classified as "common gravel," but when the work was completed it was paid for as "earth" excavation, although blasting was the cheapest method of getting it. In fairness to the engineer it should be stated that he paid the powder bill, which was quite an item; but it did not cost extra expense for that material over our unit price for "common

material." Of the above, the writer believes that all material which cannot be classified accurately in specifications should be exposed to view in test pits, and samples of classification, and referred to as such, together with unit prices of same as accurate as possible.

Classifications.—The following is from the very valuable paper by J. H. Dennis, entitled "Uniformity of Requirement and Clearness of Language in Agreements for the Graduation of Railroads," published in the *Engineering Record*, C. E., June, 1907 (p. 321).

SOLID ROCK. (Abstracts from Specifications.)

H. & H.—All rock or stone containing 1 cu. yd. or more. All other material. *Erie.*—Rock in masses exceeding 1 cu. yd., which cannot be removed by blasting. *P. R. R.*—[Same as Erie.] *B. & O.*—Rock in solid beds or masses which may best be removed by blasting. *Ches. & O.*—Rock in ledges and masses exceeding $\frac{1}{2}$ cu. yd., which may best be removed by blasting. *N. Y. C. & H. R.*—Rock in masses which may best be removed by blasting. *Southern.*—Rock in masses of more than 1 cu. yd., which may best be removed by blasting. *St. L. & N. O.*—Stone in solid masses or ledges. *C. & B. & Q.*—Stratified rock weighing 100 lbs. per cu. ft., which can only be removed by blasting. *Chi. & Al.*—Rock and rock occurring in masses which can only be removed by blasting. *Great Nor.*—Rock in place, in removing which it is necessary to resort to drilling and blasting. *A. T. & S. F.*—Rock in solid beds in its original or stratified position - - - - other material which can be removed by continuous drilling and blasting, but which is as difficult to remove as limestone. *Ill. Cent.*—Rock in solid beds or masses in its original position - - - - which may best be removed by blasting. Everything else classified as "earth" excavation. *N. P.*—All rock in masses that cannot be removed by drilling and blasting. *Mo. P.*—Rock in solid beds or masses, in its original position which can only be removed by continuous blasting.

LOOSE ROCK. (Abstracts from Specifications.)

At. & N. E.—Slate, shale or other rock which can properly be removed by steam shovel or bar, without blasting, although blasting may be resorted to on favorable conditions to facilitate the work - - - - detached masses, 3 cu. ft. to 1 cu. yd. *St. L. & N. O.*—One and detached rock lying in separate and continuous masses covering 1 cu. yd.; also all slate or other rock that can be quarried without

blasting, although blasting may be resorted to occasionally. *B. & O.*—Slate, coal, shale, soft friable sandstone and soapstone, detached masses 3 cu. ft. to 1 cu. yd. *Ches. & O.*—Shale, slate, ochre, which can be removed with pick and bar, and is soft and loose enough to be removed without blasting, although blasting may be resorted to occasionally. Detached masses 3 cu. ft. to 1 cu. yd. *Norfolk & W.*—Shale soapstone, and other rock which can be removed by pick and bar, and is soft and loose enough to be removed without blasting, although blasting may be resorted to occasionally. Detached masses 1 cu. ft. to 1 cu. yd. *Southern.*—[Same as *Norfolk & W.*] "*Big Four.*"—Shale, coal, slate, soft sandstone, soapstone, conglomerate stratified limestone in layers less than 6 in. Detached masses 3 cu. ft. to 1 cu. yd. *C. B. & Q.*—Stratified rock which can be removed by pick and bar and weighing more than 140 lbs. per cu. ft. Detached masses 3 cu. ft. to 1 cu. yd. *Chi. & Al.*—Stratified rock which can be removed by pick and bar - - - and masses between 3 cu. ft. and 1 cu. yd. *Great Nor.*—Slate and other rock, and loose enough to be removed without blasting, although blasting may be resorted to occasionally. Detached masses 3 cu. ft. to 1 cu. yd. *A., T. & S. F.*—Hard shale or soapstone - - - in original or stratified position, boulders in gravel, cemented gravel, hardpan - - - and other material requiring - - - use of pick and bar or which cannot be plowed with 10-in. plow and 6-horse team. *Ill. Cent.*—(No loose rock. Everything but solid rock classed as common excavation.) *N. P.*—Slate, soft sandstone, or other rock than can be - - - removed without blasting. Detached rock between 1 cu. ft. and 1 cu. yd. *Mo. P.*—All rock - - - which requires for its removal steam shovel or pick and bar, without blasting, although blasting may be resorted to at the option of the contractor. Detached masses 1 to 18 cu. ft.

Machine for Excavating Trenches and Foundations in Frozen Ground (Eng. News, June 17, 1909).—Used in Winnipeg, Canada. "In that city the frost penetrates to a depth of 5 to 6½ ft. Previous to the introduction of this machine, all earth excavation during 5 or 6 months of the winter had been done by hand picking or by blasting the frozen earth with black powder, the former costing about \$1.35 per cu. yd., and the latter about \$1.25 per cu. yd. down to 93 cents per cu. yd. By the machine, the cost has been reduced to from 11 to 30 cents per cu. yd. The ("Drop-Chisel") machine is illustrated.

Excavation Methods, Fourth Avenue Subway, Brooklyn (Eng. Rec., Dec. 3, 1910).—Described and illustrated.

55.—ROCK EXCAVATION.

Subject Divisions.—Under "Quarrying" (see page 419) are discussed the methods of excavating "dimension" and other stone for subsequent use in masonry construction. The present subject deals with the most approved methods of excavating *open rock cuts* and *trenches* for railways, highways, canals, sewers, etc. For subaqueous excavation, including blasting under water, see "Dredging," page 927, and for tunnel work see "Tunneling" page 933.

Open Rock Cuts.—The cheapest form of open cut is the side-hill cut (Fig. 1), in which *c* is the cut, *f* the fill, and *w* the waste. A common method of operation is to begin drilling with holes *a* at the bottom of the cut, using moderate blasts and working back in steps to *b*. But where the quantity in cut *c* greatly exceeds the fill *f*, it is often advisable to begin at *b*, using deep holes and large charges of explosives. By this means a more effective use of the powder can be had in not only loosening the rock but in wasting a large proportion of it at the same time. Solid rock is supposed to stand about "vertical," hence the drill holes *b* as shown. If the material is *seamy* and contains more or less loose rock the latter may be taken out to slope as required, but it is not necessary to take out the whole cut in the same slope.*

Fig. 1.

Drilling.—The most common form of rock cut is the "thorough" cut as shown in Fig. 2. The rock is excavated in benches, *a*, *b* and *c*, but not so regularly as shown in the Fig. unless channeling machines are used as was the case on the Chicago Canal. The rise or lift may be assumed as about equal to the tread, but this depends on the size of blocks that can be handled economically, the depth of economical drilling, the quality and character of stone and seams, and whether *horizontal* holes at the bottom

Fig. 2.

of rise are drilled to assist in blasting. The spacing of the holes may be assumed about equal to their depth, if in single row and the rock is not too hard. For trap and granite the spacing should be closer, ordinarily. The rise may vary from a few feet up to 12 or even 20 ft., the deeper holes requiring the larger drills, say 3 to 3½ ins., and operated by machine. Churn drills up to 3 ins. in dia. (1½" bar) may be used for vertical holes in soft rock, where machine drills are not available. Each drill is operated by two or more men who raise it, turn it 'round a little and let it plunge back into the hole. Sometimes the drill is loaded to give more weight and hence become more effective. For two-hand hammer drilling (one man holding and turning drill, and two men striking), the hole is usually started with a 1½ to 1¾-in. bit and using 10-lb. hammers. The dia. of bit is decreased with depth of hole, to prevent binding, and the limiting depth is about 8-ft. Octagonal bars from ½-in. to 1-in. are used. For one-hand drilling (hammer 4½ lbs.), the drills are usually 1 in to 1½ in. with octagonal bars ½-in to ¾-in. in dia. The minimum diameter of hole (at bottom) for use of dynamite is about ½ in. The hand drill is often called a jumper. Rotary drills, rotating drills, or augers are names given to (hand or machine) drills which *bore* solid holes, or annular rings around solid cores. They are generally used in the softer rocks where heavy blasts are required. Such drills can, however, penetrate almost any material liable to be encountered, instances being recorded in which borings have been made through imbedded steel rails used for foundations. Core drills

* The writer knows of an instance where a whole rock cut was taken out to slope of ½ to 1, where ⅓ of it could have been vertical, or at least ⅓ to 1.

ularly designed for well-borings, both water and oil; and for borings to determine the geological formation at different depths, of which are brought up in the form of cylindrical cores. They are either steel (hardened) or diamond (black)-pointed, for effective

Working in Rock.—Trench Excavation, for water pipes, sewers, etc., is less expensive than open-cut excavation, but less expensive than tunneling. The increase in cost over open-cut work is due (1) to the greater difficulty of drilling, per cubic yard removed; (2) to the limiting use of explosives, thereby reducing the duty of drilling, powder and air; (3) to the large proportion of excavation required *outside* of "neat trench, without added compensation; (4) to the great amount of work on the sides and bottom of trench preparatory to laying the pipe. This is discussed as follows:

Due to the large amount of drilling required, machine drills should be used where the preliminary cost, reduced to rental, is warranted by the saving in yardage. Comparing cost of operation alone with that of hand digging, a saving of 40 to 60 cents per cubic yard is often effected. The steam drill is perhaps the most commonly used for this work, but compressed air may be cheaper. Gasoline compressors are somewhat cheaper than steam compressors especially on small jobs. Electric drills should be considered where electric power is available. Larger blasts may be fired if ballasted with logs, timbers or blasting mats. The flying rocks are liable to cause damage, as in cities. Mr. H. C. Hettie in his "Rock Excavation," describes a blasting mat woven of hemp rope, 1½ in. dia. or larger. The mat is woven like a cane-air, the first set of strands being looped over 1-in. gas pipes. It is held in place by heavy timbers, thus effectively checking the progress of the fragments of rocks. The narrow outlines of the trench, however, require the duty of the charge.

In estimating the cubic yards in trench excavation it is well to allow the trench 24 ins. wider than the external diameter of pipe or culvert to be laid, and 6 ins. below grade. Bell holes have to be dug at the corners and there is more or less trimming to be done along the sides so that this seems no more than a just compensation. Engineers sometimes let contracts based on the lineal feet of pipe laid irrespective of the trench or quality of material to be excavated. This throws the responsibility of examination of the soil, etc., upon the contractor (who usually does not guess), and is not recommended. If for any reason the line of the trench is changed after such a contract has been let, complications invariably arise between engineer and contractor.

Reference has just been made to trimming up the bottom and sides of the trench to receive the pipe for laying. There is another item that should not be overlooked, namely, lowering the grade after the trench is finished. Instances are of record where contractors have been allowed to lower the grade from a few inches to a few feet at a price based on the original bid per cubic yard, whereas such work sometimes costs more than the amount received, the specifications admitting of no redress. In the above is a trench mostly in earth excavation but with a quantity of rock at the bottom. In such a case the lack of proper planning may prove very expensive to the contractor.

Excavation of Drainage Canal.—The material was classified as glacial drift (10 cu. yds.) and solid rock (12,300,000 cu. yds.). The glacial drift consisted of tough, indurated clay and cemented gravel or hardpan, interbedded with boulders and capped with prairie soil. The solid rock was of a variety of igneous rocks, increasing in hardness with the depth. All the material except the top soil, required blasting, the hardpan standing vertically like a wall. The best method of loosening the hardpan was by dynamite charged at the ends of small tunnels. Fig. 3 shows sections of the material in the two classified materials named.

The rock section is 160 ft. wide at base, and 36 ft. deep. The drills were operated mostly by compressed air at 80 to 90 lbs. pressure per sq. in., supplied by a central compressor, through 8 or 10-in. mains with 6 to 8-in. branches. The feeds were commonly supplied with 2-in. feed pipes 175 to 230 ft. long, turning into 3½ x 6½ in. cylinders. Bits of the X pattern were found to be the best. The rock was taken out in 3 12-ft. lifts (Fig. 2); and 40%

dynamite proved to be the best generally. The sticks were $1\frac{1}{2} \times 6$ ins. weighing $\frac{1}{4}$ lb., and 10 to 25 sticks were charged in a hole. The price per lb., including caps and fuse, was about 12 cents and about 1 lb. of dynamite was used per cu. yd. of rock.

Chicago Main Drainage Channel.

Fig. 3.

Channeling machines of the Sullivan and Ingersoll types were used in order to secure smooth side walls to the canal. The average machine weighed 11000 lbs., was operated on a track 30 ft. long, and struck 250 blows per min. The width of the channel cut by the bit was $2\frac{1}{2}$ ins. at the top, decreasing $\frac{1}{4}$ in. for each 2 ft. of depth. The speed of channeling was 130 to 200 sq. ft. per 10 hrs. on the upper lift (where the rock was softer) and about half as much on the two lower lifts. The lifts were 12 ft. each. The cost of the channeling varied from 8 to 25 (say 17) cents per sq. ft., or from 3 to 7 (say 6) cents per cu. yd. excavated.

Steam shovels of the Bucyrus type were employed to a limited extent in loading rocks on cars. The cars were operated by incline and hoist methods. But these were generally more expensive than the cantilever, cableway and derrick methods of conveyance as shown in the two following tables.

* Compiled by Mr. W. G. Potter. Common labor received 15 cents per hour.

Performance of Work.—A few examples* are given to illustrate methods of various classes of rock excavation, as follows:

Rock Breaker for excavating rock under water, designed by F. W. of Empire Eng. Corporation,† used in excavating (about 260000 cu. yd.) about 18 to 25 ft. under water, in improvement of Black Rock Harbor. N. Y. Contract price, \$1.85 per cu. yd. The rock is broken by a cutter of a steel cylinder 28 ins. dia., about 25 ft. long and weighing 46000 lbs., the bottom with a hardened steel cutting point. The weight is hoisted upon the rock bottom from a height of six ft. or more.—*Eng. News*, 1907, p. 236.

Drilling and Blasting Soft Shale Rock Under Water, at Ashtabula Harbor, Ohio. 85 ft. long by 30 ft. wide, held in position by four spuds, one at each end, equipped with Ingersoll-Sargent steam drills on trucks for horizontal and operated vertically by hydraulic lifts. *Drill Boat "A"* worked days of drilling and blasting 4744 cu. yds. (place measure) during month of was 28.5 cts. per cu. yd., the average depth of holes being 6.15 ft. spaced 10 ft. apart. Of this amount, the labor cost of drilling and blasting was 6.7 cts. per cu. yd. of explosives was 6.7 cts. *Drill Boat "B"* worked both day and night for the day shift was 23.6 cts. per cu. yd., while for the night shift it was only 20.4 cts. per cu. yd., there being less breeze during the night. Average amount of explosive (45%-dynamite) used was $\frac{1}{2}$ lb. per lin. ft. and costing 15 cts. per lb. The blasted material was excavated with dipper *Eng. Contr.*, Aug. 7, 1907, p. 83.

Drilling Granite in Open Cuts on the Grand Trunk Pacific R. R.—Data by Geo. C. McFarlane, eng'r and contr. Steam drills used in large cuts. Drills in smaller cuts. 1" steel to make drills gaged to 1 $\frac{1}{2}$ ", used for entire length. Gang of three men drilled per day average of 29 ft. in dark hornblende, 1 granite, and 18 to 19 ft. in trap and diabase rock. Rock-cuts 20 ft. wide on side slopes 1:4 or as material will stand. On most open cut work it has been customary to drill the blast hole on or near the center line of the cut, so as to place the charge of explosive at the center of the mass to be moved. A 12-ft. hole is 10 ft. burden, while a 25-ft. hole is given from 20 to 25-ft. burden. but Mr. used for the 20-ft. roadbed two holes 10-ft. on each side of center line, not to exceed 15 ft. After drilling, the bottom of the holes are chambered by the charge by springing with dynamite. In a bottom bench where a heavy bed, no more than a ft. is chambered. In upper benches it is permissible to 2 or 3 ft. of hole. The first springs are held down by water tamping. If, water tamping is nearly as good as sand, except when charges of over are used. With heavy charges the water tamping permits the dynamite to fill the hole and make it ragged. Sand tamping has to be drawn after each charge and sand is free from clayey material it can be drawn quickly by spudding down and pumping up the cuttings. Sometimes it can be blown out with a blowpipe. With water tamping, a cap and fuse are used, unless the hole, when the spring is made with electric exploders. The fuse, usually 10 ft., after being split is held under water for 5 or 6 seconds to kill any fire on the tape, and then dropped into the hole. Unless the drop fuse were used, it might ignite dynamite adhering to the sides of the hole, causing an explosion. After each water-tamped spring, the hole is blown out with compressed air with a sludge pump. The springing opens up the rock jointing very closely where the burden of the shot will cleave from the solid, successive springing charges indicate the ratio of enlargement of the pocket. The cost of work is as follows: (a) Fully $\frac{1}{2}$ of the rock cuts are sublet to gangs of men at from \$1.15 to \$1.35 per cu. yd. They are given free cars and rails; charged \$4.50 per week for board, \$5.50 per day for team and driver, \$11.50 for 60% dynamite, and \$2.75 per keg for black powder. (b) Cost of block of granite boulder 10 x 12 x 9 ft., containing 36 cu. yds., was (48" drill 3 lbs. 60% dynamite \$0.66, reblasting 2 fragments \$1.42) \$4.50 or 12 $\frac{1}{2}$ cts. per cu. yd. (c) Cost of block holing red granite boulder 16 x 14 at top and bottom, 15 ft. deep, containing 92 cu. yds., was (96" machine drill hole 3 lbs. 60% dynamite \$3.52, reblasting 2 fragments \$1.45) \$12.24 or 13 $\frac{1}{2}$ cts. per cu. yd. (d) Cost of blockholing black granite boulder triangular in shape, 4 x 5 x 6 ft., containing 1.1 cu. yds., was (7" hole 50 cts., $\frac{1}{2}$ lbs. 60% dynamite 8 cts.) 2 $\frac{1}{2}$ cts. per cu. yd.—*Eng. Contr.*, Nov. 27, 1907, p. 301.

Reference to articles giving more complete description are given at the end of each example.

New York City. †See also *Eng. Contr.*, Dec. 18, 1907, p. 343, for details of cutter and detailed information.

EXCERPTS AND REFERENCES.

The Well Driller for Drilling Blasting Holes (Eng. News, June 22, 1904).—On the excavation work for the Wabash R. R., in Ohio, in drilling brown sandstone the holes were put down to a depth of 24 ft. with a 3" bit, and the drill averaged two such holes per day of 10 hours. The cost of labor, fuel and water was about 12½ cents per ft. of hole drilled. In the blue sandstone, which is softer, an average of 60 ft. per day was drilled. Formerly, with churn drills by hand, the cost in brown sandstone has been 38 cents per ft. of hole, the holes being 20 to 30 ft. deep; the steam drills, up to depths of 20 ft., and in sandstone no harder, reducing this cost but very little. The well-drill holes being large (3") are never "sprung" more than three times in the sandstone, whereas the steam-drill holes (1½") must be sprung 4 or 5 times.

56.—DREDGING.

Discussion.—In estimating the cost of dredging in any locality depend upon the *amount of dredging* to be done, as well as the material, method of disposal, depth and roughness of water, climatic conditions affecting the number of working days per year, and other things. The cost of dredging may vary from 3 to 4 cents up to about 100 cents for earthy material; and for solid rock where subaqueous blasting are required the total expense of removal may amount to 100 cents per cubic yard.

There are three methods of measuring dredged material, namely, (1) by prior and by subsequent surveys or soundings; (2) in *scows*, or by displacement; and (3) in *fill*. The *first* method is generally used especially in shallow cuts where any error in average depth amounts to considerable in percentage; and again, the excavated material is almost sure to become partly filled again with current drift, and it would represent an error in yardage against the contractor. Measurements are very useful as a check in many cases. The *second*, in scows, is usually adopted and is probably the best where the object is "dredging" and not "filling" or reclamation. In this method it should not be forgotten that dredged earth will swell from 25 to 30 per cent (average say 25) and the method of measurement should conform to the specifications and contract. Scows should be self-dumping and the cost of delivering or wasting will be that of towage mainly. The *third* method of measurement is in fill where the object is reclamation. Measurements are also generally kept as a check or even as the basis for payment. The writer was employed in an engineering connection with the filling of what is now known as a part of the harbor, Boston, being the trapezium bounded by Beacon St., West St. (now Massachusetts Ave.), the Boston & Albany R. R., and the harbor. Much of the area was under water. It was cross-sectioned and soundings from rafts were taken at range and station-positions, in connection with gage (tide) readings at stated intervals. In taking the soundings (2 or 3 men at a pole) there were usually three readings, namely, top of mud, bottom of soft mud, and "stiff mud" and the filling consisted of dredged material from the Charles River, in scows as long as the depth of water would permit, then the material was brought in on B. & A. R. R. cars from gravel banks at several miles distant. The character of the mud bottom precluded the possibility of estimating the quantity of fill accurately by the method of sounding and sounding, and payments were made by scow and measurements. It was estimated, however, that the amount of material below the top of the mud was equal to from 20 to 40% of the total mud respectively. In hydraulic dredging for reclamation it is difficult to estimate "in fill" only, and it should be stated clearly in the contract.

—Any machine that will excavate material under water is called a dredge. Perhaps the simplest form of dredge is the drag scraper which is towed back and forth over the bottom by the use of cables. There are two main cables to give the bucket the correct incline for scooping material, and one back cable to steady the bucket and haul it back. The dredge is usually mounted on scows or floating hulks and may be operated by steam or electricity. The latter is seldom used however excepting in small dredging is centralized, of great magnitude, and practically continuous. In such case there may be a central power station on shore, feeding the dredges.

Dredges are usually classified according to the excavating machine, of which there are four principal types, namely, (1) the dipper dredge, (2) the

grapple dredge, (3) the bucket elevator dredge, (4) the hydraulic dredge. Each of these is particularly adapted to certain kinds of dredging and there are many modifications.

The Dipper dredge (Fig. 1) is really a long-handled dipper or shovel which is filled by pressing the scoop down into the mud while being swung radially outward. The material is dumped through the bottom of the bucket, which is movable (usually hinged). This is the best all-around type of dredge for general use. The buckets average 1 to 2 cu. yds., but may be of any size up to 6, 10 or even 15 cu. yds. capacity. They are capable of working in very soft and very hard material and are generally useful around wharves, and for channel and canal excavation. 30 ft. of water is about the limiting depth for good work.

Fig. 1.
Dipper Dredge.

The Clam-shell bucket (Fig. 2) is suspended from a derrick boom on scow and is a form of grapple dredge. The bucket is lowered with jaws open, and sinks into the mud by its own weight. The jaws are then closed around the material and the bucket is raised and dumped. The capacity of a clam-shell bucket is about the same as that of a dipper, but it is especially adapted to deep dredging.

The Orange-peel bucket (Fig. 3) is another form of grapple, and may have 3 or more segments which are open during its descent and, after pressing into the mud, are closed. In addition to its regular work in dredging, it is frequently employed in excavating inside of cylinders which are being sunk for foundations.

Fig. 2. Clam-shell Bucket. Fig. 3. Orange-peel Bucket.

The (Bucket) Elevator Dredge or bucket ladder dredge consists of an endless ladder chain to which buckets are attached. These buckets scoop up the material from the bottom, are elevated to the top of the ladder, and the material is dumped in a chute or on a belt conveyor which deposits it as required. They are particularly adapted to "skim" dredging in soft material for canal work, etc. They leave a smooth bottom. The buckets may have a capacity of say $\frac{1}{10}$ to $\frac{1}{8}$ cu. yd. each, and a speed of 30 to 40 ft. per min.

For discussion of sub-aqueous electric power cable, see *Eng. News*, May 7, 1903, and Aug. 13, 1903.

The Hydraulic Dredge* is used in the improvement of waterways and in the reclamation of low lands. It works best in fine material which remains suspended in a swift-moving volume of water. The principal features of the hydraulic dredge are the rotary cutter or stirrer to loosen the material and keep it in suspension, and the centrifugal pump to pump the suspended material up into the delivery pipe and to its destination. If the material is light and loose the rotary cutter is sometimes replaced by the water-jet, but ordinarily the cutter is better, and must be used on compacted materials. Sand is handled easily, but if it is sharp and hard it wears out the pumps quickly. Coarse gravel is out of the question. Soft clayey mud is probably the best. The delivery pipe is of sheet iron or steel (sometimes wood-stave pipe), with an average diameter of say 10 to 20 in.

* For valuable data on Dredges, see *Eng. News* of July 28, 1904.

be 2000 to 3000 ft. in length. Between the dredge and the shore are pontoons, either single or double.

Working "with" and "against" the current of a stream are subjects for consideration, and depend somewhat on local conditions.

Working Under Water is required in removing ledge rock and large boulders. The following is from Gillette's "Rock Excavation," from data by C. Y. Dixon, U. S. Ass't Engr.:

At the mouth of the Detroit River it is usually necessary to drill and blast the bottom before it may be excavated. The drill boats in use (1903) are from 60 to 100 ft. long, and from 25 to 30 ft. wide, and are held in position by four "spuds," one at each corner. They are equipped with two or more Ingersoll steam drills supported on frames having trucks to permit of the drills being moved horizontally along the side of the boat. The drills are raised and lowered during the operation by cable lifts. The boiler furnishes the steam for operating the drills, the engine in connection with the hydraulic lifts, the forge the electric light plant and the machinery with which the ordinary drill boat is equipped. The holes, 4 to 6 in. in dia., are made at the corners of 5-ft. squares to a depth of about 10 ft. the required depth, at the rate of about 5 ft. per hour per drill. One pound of dynamite is used per lin. ft. of drill hole. The holes are charged by inserting a charge of dynamite with the exploder and battery wires attached to the bottom of a hole. The battery wires lead out through a slit in the side of the pipe. This pipe is drawn into the drill hole, the dynamite shoved down with a long ram-rod, and the pipe withdrawn, a wire spring clamped to the dynamite stick preventing its coming out of the hole. The wires are then attached to the battery and the dynamite exploded. During this operation the drill boat is not moved, nor does the work of the other drills cease except at the time of firing. On two occasions, the charge of dynamite came out of the hole, and was exploded directly in front of the boat, causing it to sink almost immediately. This was due to carelessly pulling the wires up taut they will indicate whether the charge is in place. A supply is kept at the drill boat, stored in a small scow trailing down a safe distance. Dipper dredges are used in excavating the material. They are in length from 80 to 135 ft. and in width from 30 to 40 ft., and are held in position by three spuds (36 in. square), two at the bow and one at the stern. The entire width of the area to be improved has been worked over by the dredge by cut, the derrick scow follows after to remove such loose pieces of material as have been left projecting above the required depth. The derrick scows are from 80 to 100 ft. long and from 20 to 25 ft. wide and they are equipped with a derrick hoisting engine and derrick capable of lifting from 12 to 18 tons, and a complete diving outfit. When lifting the boulders, the derrick scow is pinned to the bottom on two spuds, each about 1 ft. square. The material to be moved is hoisted by means of an iron bar, about 30 ft. long, suspended from the side of the dredge to the required depth. Any obstruction struck by this bar, as the scow is swept across the improved area, is removed by the derrick by means of a chain, which is attached to the position by a diver.

The following summary of the above will be of interest. It should be noted that at Ballard's Reef was limestone bedrock, clay hardpan (50%), and at Lime Kiln Crossing was limestone bedrock; at Lime Kiln Crossing was mainly limestone bedrock, with no overlying material; at Amherstburg the material was limestone bedrock, clay and boulders, with generally two ft. of loose material above.

Gold Dredging.—This has become a very profitable industry of the streams of California. Mr. W. P. Hammon, who has experience in this class of work, writes the author from March under date of Sept. 12, 1906, as follows:

In handling gravel in our work we use elevator dredges entirely dredge not being so efficient or economical; in fact, in most places the latter is altogether impracticable for the reason that where boulders are frequent, in the operation of a hydraulic dredge, the nest at the intake of the suction pipe thereby preventing gold from flow of water.

We have operated elevator dredges with steam and electric power from our experience consider that electric power is at least 50 per cent economical, to say nothing of the great convenience electricity has. Our estimate is based on power at 1½ cents per kilowatt-hour, and work aboard ship.

Performance of Work.—The following examples are given mainly for reference to the articles themselves, in which complete details and illustrations are given; the abstracted matter being sufficiently full to present to the reader some idea of the nature of the article, and to bring out some points in the design and execution of this class of work.

Powerful Dipper Dredge "Majestic" with Edward Cable-Storage Drum. Designed and built for Edward Bros., of Sault Ste. Marie, Mich., sub-contractors on improvement of the West Neebish Channel in the St. Mary's River, Mich. Dimensions, 116x40 ft., and 13 ft. deep, with two steel trusses 24 ft. deep extending the full length. Steel boom 60 ft. long, stepped into a steel casting at the bow supported by four cables $2\frac{1}{2}$ ins. dia.; boom swung by two 2-in. cables on a horizontal cable. Dipper handle 54 ft. long and weighing 15 tons; with 5-ft. dipper capable to a depth giving 30 ft. of water; operated by horizontal engine of 100 P. H., capable of exerting, through the gearing, a pull of 200 tons upon the cable, and of dredging solid beds of soft limestone rock without blasting. Spuds are 43 ins. square by 52 ft. long, each composed of four sticks dressed and fitted into cast steel shoe at bottom and bolted together for 8 ft. from bottom with 24 bolts $1\frac{1}{2}$ ins. in dia. At the top, the sticks are held together by and $\frac{3}{4}$ " x 10". For the intermediate space there is no bolting, the timbers are so as to give a certain flexibility or spring. The spud foot is 10x12 ft. of timbers 16 ins. square. The dredge can be lifted about 2 ft. above its position, by means of a 2-in. cable running over the top of each spud, thus elevating the spuds from 2 to 6 ft. into the mud. The capacity of the dredge is about 100 cu. yds. per hour in rock alone, and about 10 times that amount when working in soft material and using an 8-yd. dipper. The Jackson & Church Co., of Detroit, Mich., controls the patents for the Edward cable-storage drum, which requires a cable about 1000 ft. long to be used, and when this breaks, only about 100 ft. are lost, the working length being replaced by paying out sufficient cable from the storage part of the drum.—*Eng. News*, Feb. 7, 1907, p. 145; and Oct. 10, 1907, p. 173.

Discharge Pipe of a Dredge. Device used in dredging the harbor of New York. The 24-in. pipe line was suspended from pontoons made of pairs of timbers built of boiler plate, water-tight, and from 10 to 80 ft. in length. The pipe of cylinders is fastened together by timbers under which the discharge is made, the latter being laid with flexible joints at intervals, for the necessary length of material is delivered from 1000 to 3000 ft. from dredge.—*Eng. Contr.*, Sept. 1906, p. 160.

Centrifugal Dredge "Onelda," used on the New York State Barge Canal. Designed by Mr. Emile Low. Designed by Mr. Lindon W. Bates, Pres. the Empire Canal Corporation, contractors. Length over all, 97 ft.; extreme beam, 17.5 ft.; depth to deck, 10 ft.; light draft, 5.5 ft. Can be taken through locks, on pipes, on sides, extending from centrifugal pump aft to cutter forward; dimensions, 19 $\frac{1}{2}$ ins., No. 9 B. W. G. metal, connected forward to two Bates curved suction joints. Two movable suction pipes or suction ladders are built-up pipes, having an area of 291 sq. ins., at the lower ends of which are attached the cutters 5 ft. 6 ins. dia. and 3 ft 8 ins. high. The cutters and dredge are illustrated in *Eng. News*. When working, pontoons are attached to side of dredge to float it. During Oct., 1906, 38173 cu. yds. were dredged at cost of 50.5 cts. per cu. yd.; during Nov., 1906, (two weeks spent in repairs), 144 882 cu. yds. were dredged at cost of 30.8 cts. per cu. yd.—*Eng. News*, Dec. 5, 1907, p. 619.

Centrifugal Dredge "Francis T. Simmons," used in Lincoln Park Reclamation on the Michigan. Dredge designed by Mr. A. W. Robinson, and built by Atlantic City Co., 111 Broadway, New York City. Hull, 148 ft. long, 38 ft. wide, and 13 ft. deep. Main pump has 30-in. suction and discharge, and main engines are triple expansion marine type of 1200 I. H. P. There are two double-cylinder boilers 11 ft. 6 ins. x 18 ft. long with eight corrugated furnaces. The dredge is carried by a very strong steel frame, and is fitted with a powerful digging the clay. A capacity of 3000 cu. yds. per hour in clay is said to have been reached.—*Eng. Contr.*, Dec. 25, 1907, p. 356.

EXCERPTS AND REFERENCES.

Methods of Measuring Dredged Material in the Channel Improvement of the Delaware and Schuylkill Rivers (C. H. Ott. Proc. Engrs. Club, April number; *Eng. News*, July 3, 1902).—Illustrations of sound-submerged sweep used with rowboat, and sweep and derrick used on barge. Description and methods used.

The Fruhling System of Suction Dredging (By John Reid. Eng. News, Mar. 5, 1908).—Table of comparison of this type with American hydraulic hopper dredges.

Large Elevator Dredge for Work in Boston Harbor (Eng. News, Jan. 27, 1910).—Capacity of each bucket is $1\frac{1}{2}$ cu. yds. and the bucket chain is driven ordinarily at a rate of 14 buckets per min., so that the dredging capacity with full buckets would be 1,100 cu. yds. per hour. This has been exceeded by more than 30% for shorter periods in actual use. For driving the bucket chain, a double tandem compound steeple engine is provided, with cylinders 12×16 ins. by 18-in. stroke. This is entirely separate from the engines for driving the vessel's propeller shaft. The ladder frame is of steel and is of sufficient length to work at a depth of 51 ft. After a year's service, the buckets with their pins and bushings are reported in good condition and the general loss of time and cost of repairs is said to compare favorably with that of a dipper dredge on the same class of work. The material encountered at different parts of the channel included hardpan, clay, stone and gravel. The ordinary yardage for a single day's work was about 8,000, and under favorable conditions as much as 10,800 cu. yds.

Working Costs of Gold Dredging in California (By Charles Janin and W. B. Winston. Mining and Scientific Press, July, 1910).—The total operating expense per cu. yd. varies from 9.23 cts., for difficult digging, down to 2.30 cts. for easy digging (fine gravel).

57.—TUNNELING.

Definitions.—In a broad sense, a *tunnel* is an artificial underground and *tunneling* treats of the methods of construction, embracing all processes of excavation, timbering and lining. Either or both of the words may sometimes be omitted as when the excavation is through solid rock. Tunnels are usually horizontal or nearly so; but they may be inclined in any direction: a vertical tunnel is called a *shaft*. For the purpose of enlargement, a small tunnel projected ahead of the full section is called a *heading* if in upper part of section,* and a *drift* if at bottom of section. A *loop heading* is a small auxiliary tunnel loop from the main tunnel. In blasting, the quantity of rock which should be loosened by a charge of powder is called the *burden*. *Muck* is a term applied to excavated material (including broken rock) from a tunnel.

Classes of Tunnels.—Railway-, highway-, subway-, aqueduct-, mining-, sewer-, ventilation-, sub-aqueous-.

Methods of Tunneling.—There are many methods in use—some of them national or provincial—dependent upon the class of material to be excavated, the machinery available, the position of the tunnel, and local circumstances:

- cut, dry tunneling—for subways, etc.
- cut, dry tunneling (including the deep subaqueous-).
- solid rock, by headings or by drifts.
- common earth, by driving full section at once; by driving either the upper or the lower half first; by leaving a middle core sub-pillar to be taken out last.
- cut, wet tunneling—not subaqueous.
- cut, quickstand, by shield or by freezing process.
- cut, aqueous tunneling—not deep.
- cut, by shield—with or without compressed air.
- cut, re-bottom tunneling—by dredging, and—
- cut, constructing coffer dams.
- cut, sinking caissons.
- cut, aqueous "tunneling." (Proposed for English Channel but not adopted.)
- cut, tubes suspended, supported, or sub-floated in water.

Cut Tunneling.—Much of our modern subway construction is done at least, by the open-cut method, if the required cutting is not too great. The sections to be built are opened up in convenient lengths of 100 or more, and the street traffic is supported on wooden framework of timbers and processes of excavating and lining the tunnel. The construction is somewhat analogous to that of a big sewer, but much more intricate. The sides of the cut may be shored up by sheet piling, say 2½ ins. thick, and behind longitudinal girts braced apart by transverse struts of 10 x 12 timbers with single or double wedges at the ends (see Fig. 1). The end portals also may be constructed in open cut, or as by the shield method. In Europe the practice is to construct the portals first, while in the United States they are finished after the main tunnel is completed.

Open cuts were formerly very rare at depths of more than 65 ft., for any considerable distance, but the practice is quite common to run them at 80 ft. in depth.

"Cutting" vs. "Drift" Method.—The first named is the distinctive American tunneling. A wedge of rock is first blasted out on the top of the section, by drilling two rows of holes with the drills.

Sometimes the term "heading" is used in a broad sense as applying to any tunnel smaller than the full section.

Fig. 1.—Shoring.

converging toward each other at their points. This "center cut" is then widened laterally into a "heading" from which the bench below is easily worked by vertical drilling supplemented by horizontal drilling at the sides of the section. Sometimes a central core is left to support the centering temporarily. There are various modifications of the above. They differ essentially however from the prevailing European method of first driving a "drift" at the *bottom* of the section and working *upward*. In either method, where possible, the work progresses in benches so two or more drilling gangs may be employed at the same time. Headings and drifts are often advanced a few hundred feet beyond the main, full section—sometimes a thousand feet or more.

Drilling and Blasting.—Hand drilling, and even steam drilling, is being supplanted by drills operated with compressed air or electricity. Where the necessary water power is available hydraulic drills are used, and sometimes show great economy over any other power; at the same time each drill is supplied with a jet of water for cleaning out the hole and laying the dust in the tunnel. Compressed air has the advantage of incidentally ventilating the tunnel. Electricity becomes economical as the depth of tunnel increases from the face or portal.

Drills may be mounted on tripods, on cars, on columns (one or two drills to each column) which brace against the top and bottom of the tunnel and have a wide range of action, on bars which brace against the sides of the tunnel, etc. The size of an *air* drill is denoted by the inner diameter of the cylinder.

Dynamite of high grade, say 75% down to 60 or 50, is used in center-cut blasting in hard rock, as granite, trap, basalt, syenite, gneiss, etc., while for soft or seamy rock and for trimming up on the sides of the tunnel a lower grade of dynamite, say 40%, is better.

The "Radialaxes" channeling machine, manufactured by the Ingersoll-Rand Co., has been used to some extent, and its general efficiency will be watched with interest.

Timbering.—In hard, solid rock, timbering is not required and the finished tunnel is often left rough without lining. But in loose, seamy rocks and in the common soils, the sides and roofs have to be supported. Round timbers are generally used for timbering because they are cheaper, although sawed timbers are more easily framed and handled. In very loose material, lagging or sheeting is driven longitudinally of the tunnel behind transverse, segmental girts, or it may be driven transversely behind longitudinal girts. The girts are supported by timber props or struts, size about 12 x 12 ins. if sawed. Another method is to omit the lagging and lay the longitudinal girts close together, supported by segmental ribs of timbers. If these segmental ribs are placed close together even the girts may be omitted. Figs. 2 and 3 show simple types of rafter timbering in small tunnels in which the lower space is left open.

Fig. 2.

Fig. 3.

Lining.—The lining may be of timber, brick, stone masonry, concrete, etc. In subaqueous work the lining is frequently of cast iron, steel or reinforced concrete. The thickness of plain concrete or brick lining in the upper or arched section will of course depend largely upon the kind of material through which the tunnel is driven. In *loose* material of considerable depth the thickness of the concrete lining may be *assumed* at not less than 2 ft. for a single track railroad tunnel, and somewhat more for a double track tunnel. This thickness increases gradually in the lower bench walls,

middle of the section, to about 150% neat thickness at the foot-
 g. 4 is a section of the *Gallitzin tunnel through the Alle-
 n the Pennsylvania R. R.
 foundation footings are sometimes very expensive and difficult, if
 averts, seamy rock or soft material If the last named is en-

Fig. 4.

the side walls are frequently continued below the track in the
 inverts or inverted arches, of concrete; and "weep holes" should
 be in the lower part of the walls to drain off the surplus of outside
 water which if allowed to accumulate might cause undue pressure on the
 lining, softening the sustained material.

Alignment and Grade.—The following remarks apply particularly to
 tunnels:

Right alignment conduces to economy in both length and sectional
 area of tunnel; and in cost of excavation, timbering and lining, per unit
 of material as well as in total. It also minimizes cost of operation,
 and the risk of accident. Curves may be introduced when other con-
 siderations outweigh the above, or from necessity.

Drainage is absolutely essential in long tunnels, for drainage. As tunnels
 are generally at the highest points of the lines the grade summits are
 usually near their centers, so that in driving the tunnels up-grade
 the ends are drained naturally. If it is assured, however, that
 the heavy freight traffic will be in one direction it might be better
 to drive the whole tunnel on a down-grade in that direction, thus reducing
 the nuisance (aiding ventilation) and the chance of trains being
 stopped for drainage, a grade of about 2 ft. per mile is the minimum—
 1 mile is better.

Ventilation.—The greatest difficulties met with in the ventilation of
 railroad tunnels are during their construction. It is estimated
 that a workman fouls about 25 cubic feet of air per minute; and a horse

5 or 6 times as much. If we add to this about 10 cubic feet per man for fouling by dust and gases from explosions, we have a basis for estimating the *minimum* number of cubic feet of air which must be supplied at the heading. This must be increased when men are working in different parts of the tunnel and also when locomotives are employed to handle the cars. The purity of the atmosphere can be aided materially by the use of compressed air drills and also by the use of the water jet in the drill holes and by water sprinkling elsewhere to lay the dust. The carbonic acid gas exhaled in breathing may be augmented by "fire damp" or carburetted hydrogen gas which lies pocketed in rocks in the coal measures, sometimes encountered by railway and other tunnels.

Vertical shafts in tunnel construction are sometimes sunk to increase the number of headings and push the work, but the cost of sinking them and the subsequent cost of handling tunnel excavation through them is very great. These shafts are left open for ventilation after the tunnel is completed. It is a serious question however whether they are of much value for this purpose. The best ventilator is an express train running down-grade through the tunnel and emitting little or no (black) smoke, in which case the tunnel shaft is not only of no aid but a positive hindrance to clearing the tunnel. A central shaft is sometimes beneficial if located in about the middle of a very long tunnel which point also happens to be the summit of two ascending grades; but usually where the whole tunnel is on one grade the shaft is rather a drawback. Artificial ventilation is accomplished usually by forcing air through pipes to the center of the tunnel, or by suction at the ends (through closed doors), or both. With the advent of electricity in the operation of trains the difficulty disappears.

"Shield" Method.—This method is employed in boring subways and subaqueous tunnels. The shield consists of a cylindrical steel shell with a cutting edge pressed against the head of the tunnel to be excavated. A detachable hood is provided, when boring through gravel and sand, to replace the upper and side portions of the cutting edge. As the excavation progresses, the whole shield is pressed forward by hydraulic jacks or shoving rams; and in order to preserve true alinement in the finished tunnel it is necessary to steer the shield by exerting more pressure on some of the jacks, thereby giving the shield a certain "lead" or angular direction, either laterally or vertically, or both. It is sometimes necessary also to give the shield a constant lead in one direction in order to produce a true alinement when passing through certain classes of material. For subaqueous tunneling, where compressed air is used, the shield is a very complicated machine, and the progress of the work hinges largely on its proper design.*

"Dredging" Method.—This method was employed by McMullen & McBean,† sub-contractors, in the construction of the west half of the river portion of the Harlem River Tunnel, New York City, for the Rapid Transit Railroad. Mr. McBean describes the work as follows:

First a channel was dredged across the river bottom to within a few feet of the full depth of excavation required to build the tunnel. In this channel, foundation piles and a row of specially prepared heavy timber sheeting, along each side and across the ends, were driven and cut off to a true plane about 25 ft. below the surface of the water. This sheeting forms the sides and ends of a pneumatic working chamber. For the roof of this chamber a platform of timber 40 ins. in thickness and extending the full width and length of the tunnel section, was built and sunk and rested on the cut off sheeting which formed the sides and ends as above described. Simultaneously with pumping the water from under this roof, compressed air was forced into the chamber under a pressure corresponding to the pressure of the water above the roof. Inside this chamber the west half of the tunnel was built and then the timber roof was removed.

"Caisson" Method.—This consists in building and sinking caissons to the required level below the surface of the river bed and later connecting them together so that they form sections of the completed tunnel. See *Eng. News* of Feb. 15, 1906, and April 11, 1907, for illustrated description of

* See articles on "The Construction of the Pennsylvania R. R. Tunnels Under the Hudson River at New York City," by James Forgie, in *Eng. News* of Dec. 13, 1906, and Feb. 28, 1907.

† Mr. D. D. McBean is credited with the design of this method of tunneling.

od, proposed by Mr. L. Chagnand, a Paris contractor, and applied in the construction of a tunnel crossing the Seine on Line 4 of the Metropolitan Railway of Paris. It may be noted here that in connecting the sections in place, the "Freezing" method is proposed. The first tunnel measured 54 ft. wide, 41 ft. high, 118 ft. long, and weighed 100 tons, without the cast iron lining. See also *Le Genie Civil*, Dec. 2,

Performance of Work.—References are given here to recent tunnel construction under the most approved methods; particular pains being taken to draw the attention of the young engineer to the various classes of work encountered.

Building Subways in New York City.—Nearly four pages devoted to the construction of about $\frac{1}{2}$ -mile section of Brooklyn extension. Cost, including plant, about \$100,000. Some of the unit costs are: Earth excavation, \$3.62 per cu. yd.; concrete for foundations, \$4.61 per cu. yd.; steel arches, \$7.69 per cu. yd.; steel work, about $3\frac{1}{2}$ cts. per lb. in place; lining, about \$24.59 per cu. yd.—*Eng.-Contr.*, Feb., 1906, p. 29.

Small Rock Tunnel, 9 ft. diam. and about 3000 ft. long. About 2.46 cu. yd. excavation, in hard trap rock, per lin. ft. of tunnel. Total cost, including depreciation, repairs, etc., \$9.36 per cu. yd. or \$23.02 per lin. ft. 75% dynamite. Data by F. L. Pruyn.—*Eng.-Contr.*, May 16, 1906.

Watskill Aqueduct of the Additional Water Supply System of New York City.—Three pages of descriptive matter, with illustrations of standard types of tunnel: in dry loose earth, on embankment, for grade tunnel (timbered and rock), and for Hunter's Brook siphon (single and double ring sections).—*Eng.-Contr.*, Dec. 19, 1906.

Lawrence Ave.) Intercepting Sewer.—Length of land portion, Lake Michigan to Chicago River, 8220 ft., through clay. Internal dia. of lining, 16 ft.; dia. of shield, 20'-1"; brick lining in 4 rings, backed with solid timbering. Contract price, \$79.50 per lin. ft. Article contains about $2\frac{1}{2}$ pages of descriptive matter relating to methods and cost, with illustrations of draw knives.—*Eng.-Contr.*, Feb. 6, 1907.

Performance of Work in Lowering the Tunnels under the Chicago River.—About three pages of descriptive matter, illustrated. Tunnels at Van Buren, Washington and Adams Sts. to be lowered to meet Federal Government requirement for 26-ft. depth of 17-ft. depth heretofore maintained.—*Eng. News*, Sept. 13, 1906, p. 1907.

Subways in British Cities and in Paris.—Over four pages, with numerous illustrations.—*Eng. News*, Mar. 14, 1907.

Collapsible Steel Centering for Concrete Conduit Work.—Illustrated. Used for sewer work.—*Eng.-Contr.*, Feb. 13, 1907.

Use of Relining the Hodges Pass Tunnel, Oregon Short Line Ry.—Two pages of illustrations.—*Eng.-Contr.*, Feb. 20, 1907.

Shield Tunnel under Thames River, at London, Eng.—Four pages with illustrations including plans of shield.—*Eng. News*, Dec. 19, 1907.

Methods of Drilling and Mucking in a Rock Tunnel.—Abstract of article in May, 1907, of *Mine and Quarry*,* by W. P. J. Dinmore. An interesting article of 12 pages, illustrated, treating of the plan of work, arrangement of drill holes, ventilation, etc.—*Eng.-Contr.*, Jan. 1, 1908.

Notable Tunnels.—The following data have been compiled from various sources:

Jura Tunnel.—Twin single-track R. R. tunnels Nos. 1 and 2, 55.76 ft. apart, through Alps between Bâle, Switzerland, and Iselle, Italy, on line of Jura Railway. Length 19729 meters = 64728 ft. = 12.26 miles. Tunnel No. 1 constructed 1898-1905 with clear width of 14.75 to 16.4 ft., and height above rail, 25 ft. sectional area, 250 sq. ft.; cost \$180 per lin. ft.; drift method; thickness of lining, 14 to 24 inches. Tunnel No. 2 was simultaneously put through as a head-tunnel for ventilation and drainage; to be enlarged later.

Gothard Tunnel.—(1872-82.) Double-track R. R. Between Goschenen and Erstfeld, Switzerland. Length 48887 ft. = 9.26 miles. Clear width 26.24 ft.; clear height 28 ft. Cost \$246 per lin. ft.

Mont Cenis Tunnel.—(1862-71.) Double track R. R. Between Fourneau, France, and Bardonecchia, Italy. Length 42157 ft. = 8 miles. Clear width 26.24 ft.; clear height 28 ft. Cost \$380 per lin. ft.

Wipac Tunnel.—(1880-84.) Double-track R. R. Austria-Switzerland. Width 25 ft. Clear height 25 ft. Cost \$208 per lin. ft.

Troy and Greenfield R. R.—(1854-76.) Double-track; Troy and Greenfield R. R., Mass. Length 181 ft. = 4.75 miles. Clear width 26 ft.; clear height 21 ft. Cost about \$100 per lin. ft.

Cascade Tunnel.—(1897-1900.) Single track, through Cascade Mts., on Great Northern Ry. Length 13813 ft. = 2.62 miles. Clear width 16 ft.; clear height above base of rail, 21.5 ft. Concrete lining, 2 to 3½ ft. thick, replacing temporary timber lining.

Stampede Tunnel.—(1886-88.) Single track, through Cascade Mts., on Northern Pacific R. R. Length 9850 ft. = 1.87 miles. Contract price \$118 per lin. ft., without masonry lining.

Busk Tunnel.—(1890-93.) Single track, through Rocky Mts., on Colorado Midland R. R. Length 9395 ft. = 1.78 miles. Clear width 15 ft.; clear height 21 ft.

Musconetcong Tunnel.—(1872-75.) Double-track R. R., on Easton and Amboy (L. V. R. R.). Length 4879 ft.; clear width 26 ft.; clear height 21 ft. [H. S. Drinker, author of "Tunneling," was a resident engineer on this work.]

Detail Tunnel Costs in Tunnel No. 7, Los Angeles Aqueduct (By Harbards. Eng. News, Nov. 18, 1909).—Finished cross-section of 1, with 8-in. concrete lining, 8 ft. 6 ins. wide and 10 ft. 6½ ins. high. Over-breakage was 17%, making 6½ cu. yds. broken material tunnel. Total cost of tunnel, timbered and ready for lining, per lin. ft. **Drilling.**—Done by No. 7 Leyner drill, water being through the hollow steel. Drill used approximately 66 cu. ft. free n. at 83 lbs. pressure, drilling holes to 10 ft. in depth. During period 150 holes were drilled, aggregating 1203.3 ft. in length; average hole being 8 ft. Average speed of drilling was 21.74 ft. hole per actual drilling time, or 15.84 ft. per hour if lost time is included: ins that the average 8-ft. hole was drilled in 22 mins. Average drilling was 3.6 cts. per ft. of hole. **Explosives.**—There were used 1½-in. 40% gelatine; 250 lbs. 1-in. 40% gelatine; and 150 lbs. gelatine; a total of 1,050 lbs., or 11.6 lbs. per lin. ft. of tunnel, or 1 cu. yd. place measurement. Cost (del.) was \$140.87. Adding (2,700 ft., \$13.85) caps (306=\$2.49), and tamping stick (\$0.48), total cost \$157.69, which is about \$0.50 per cu. yd. place measure—\$0.27 per cu. yd. loose. Tables of detailed costs are not reproduced

58.—SURVEYING, MAPPING AND LEVELING.

Care of Instruments.—The correct use of surveying instruments takes into consideration their lack of precision. No instrument, however carefully it may be adjusted in the shop or field, will remain permanently accurate with ordinary field use. New instruments hold their adjustments better than old ones because the parts of precision are less worn. With good care in handling, the life of an instrument can be doubled without decreasing its duty. For the Level, there is but one main object of adjustment, namely, to preserve a *horizontal plane of sight* around a vertical axis. For the plain Transit it is necessary, in addition to the above "horizontal plane" adjustments, to preserve a *vertical plane of sight* passing through the point of the suspended plumbbob. Note that when the instruments are out of adjustment these "planes" of sight are warped into "cones" of sight, with the apex of the cone at the center of the telescope; hence the adjustments consist in changing "cones" into "planes" of sight.

To Adjust the Level.*—In running a line of levels, if the back-sights and fore-sights are of equal length the results of the leveling will be accurate even if the instrument is out of adjustment, as shown in Fig. 1. Thus, the elevation of each of the turning points at *R* will be accurately determined, but the "height of instrument" in each case will be wrong because the lines of sight are not level. For general leveling, however, the instrument should be adjusted so that all sights will be level.

Fig. 1.

First, the cross-hairs, or line of collimation.—"Set up" the level firmly (although it need not be accurately leveled) with one diagonal pair of leveling screws *l* in line with the telescope. Open the clips *c c*, Fig. 2, so the tele-

Fig. 2.—The Level.

scope will be free to revolve in the *Ys*. Adjust the eye-glass *e* by the milled head *e'*, so the cross hairs appear distinctly. Sight the telescope *T* on a distant point (at the intersection of horizontal and vertical lines) about 50 to 300 feet away, as this is the usual length of sight for accurate leveling. Move the object glass *o* by the milled head *o'* so that the object is seen distinctly without "parallax" (i. e., without the cross-hairs "dancing" or appearing to move away from a straight line of sight). With the bubble above the telescope, as shown in the illustration, move the line of

* See also "peg-adjustment" described in the fourth adjustment of the transit, p. 944.

sight, by means of the leveling screws *l* and the tangent screw *t*, so the intersection of the cross-hairs will cover the distant point. Now, theoretically, if the telescope is revolved in the Ys by revolving the bubble tube completely around it, the cross-hairs are in adjustment if their intersection continues to cover the distant point. That is, the line of sight is along the central axis of the telescope and pierces the center of the object glass. When either cross-hair leaves the distant object it is out of adjustment. The cross-hairs are stretched across a circular, movable ring or diaphragm, called the *reticule*, held in position by four adjusting screws *s*. To move the horizontal cross-hair upward, loosen the top screw and tighten the bottom one. (See also Fig. 6.) The reverse operation will lower it. Similarly, the vertical cross-hair can be moved laterally by the two side screws. These

Fig. 3.—Level Telescope.

screws are turned with capstan or adjusting pins. To adjust the horizontal cross-hair bring it on to the distant object, with the bubble tube below the telescope; revolve the telescope half round, in the Ys, bringing the bubble tube above; correct *one-half* the variation from the distant object, by operating the top and bottom screws *s*. Repeat until accurately adjusted. The vertical cross-hair can be adjusted in the same manner.

Second, the bubble tube.—With the clips *c* open as before, level the instrument and lightly clamp the telescope over one set of leveling screws *l*, by means of the tangent clamp. Now level the bubble *B* accurately, gently lift the telescope out of the Ys and set it back reversed, end for end. If the bubble is still level it is in adjustment. If it moves either way from a central position it is out of adjustment. Correct *one-half* the variation from the central position with the leveling screws and the balance by operating the capstan nuts *n* at the right-hand end of the tube as shown in Fig. 2, thus rising one end of the tube to a level position. Repeat (after leveling the instrument again with the leveling screws *l*) until the bubble remains central in the tube upon reversing the telescope in the Ys.

Third, the Ys.—In the two previous adjustments, we have fixed the line of sight centrally through the telescope, and adjusted the bubble tube parallel with it. It now remains to adjust the Ys, in which the telescope rests, to the same level, so that when the instrument is leveled up the vertical center pin will be truly vertical, and the line of sight truly horizontal in any direction. To do this, level up the instrument carefully, and start with the telescope over one set of the leveling screws *l*. With the telescope clamped firmly in the Ys, swing half round on the vertical center pin so the telescope will rest over the same screws but reversed in direction. Correct *one-half* the variation of the bubble, from the central position, with the leveling screws *l*, and the balance by means of the large capstan nuts *N*, operated with large adjusting pins, and similar to the nuts *n* described in the second adjustment. (Level up and) repeat, with the same screws, until adjustment is effected. The adjustment may be repeated over the other set of screws in order to test the workmanship of the vertical center pin and bearings, but it is rarely done.

To Adjust the Transit.—Even with a transit considerably out of adjustment, leveling can be done by using equi-distant back- and fore-sights; straight lines can be run by half-revolving the alidade (commonly called

half around") between reversals of the telescope; and angles can be read by the method of continuous readings (called "doubling") the "vertical" cross-hair is not perpendicular, by proper inclination of the telescope. But the only safe and proper way is to keep the instrument level. There are four or five principal adjustments, as follows: the plate-bubbles.—The two bubbles *bb* are usually set at right angles to one another, one on a pair of standards and the other on the horizontal plate. When the bubbles are adjusted and are central in the horizontal plate, the central axis or center pin of the transit is *vertical*. To adjust

Fig. 4.—The Transit.

the bubbles, revolve the alidade so the bubble will be parallel to the horizontal plate; level the instrument; revolve the alidade 180° and correct *one-half* the *variation* of the bubble from its central position, by the leveling screws *l*, and the other half by raising or lowering one end of the tube, using the adjusting pin in the capstan screw or nut at one end. Repeat until the bubble remains central in the horizontal plate when the alidade is revolved. The other bubble is adjusted

Fig. 5.—Transit Telescope.

the standards.—In order that the telescope will revolve about a true vertical circle, the standards *s* must support the *axis* of the telescope in a perfectly horizontal position. In some instruments there is a screw for raising or lowering one end of the axis in the standard, while in others there is no adjustment possible without returning the instrument to its original position. To test the standards, level the instrument, sight on some distant object, clamp the instrument against lateral movement, revolve

the telescope vertically downward and fix a *low* point on the line of sight. Now revolve the alidade 180° , sight again on the high point and get another low point beside the first one. A point midway between the two low points will lie in a vertical plane passing through the high point. The adjustment can then be made on the standard, using these two fixed points.

Fig. 6.

Third, the vertical hair or line of collimation.—By the two preceding adjustments we have secured a vertical axis for the alidade, and a horizontal axis for the telescope. It now remains to adjust the vertical cross-hair in the telescope so that in revolving through a vertical circle the line of sight will describe a vertical plane instead of a "cone," or in other words, so that a straight line may be produced by "reversing the instrument" (telescope). Set up the instrument on fairly level ground. Sight on a fixed point *a*, Fig. 7, reverse the telescope vertically, and set a point *b* on line in the opposite direction from *a*; revolve the alidade 180° , set the instrument again on *a*, reverse the telescope, and set a point *c* on line opposite the point *b*. Correct the vertical cross-hair by moving it laterally so the line of sight strikes *d* ($cd = \frac{1}{2}cb$). This is done by operating the side capstan-headed screws *c* which move (laterally) the diaphragm ring or reticule to which the cross-hairs are attached. Repeat the whole operation until, on reversing, the first and second points (*b* and *c*) coincide at *e*, on the straight line produced. If the "vertical" cross-hair is not truly perpendicular (which can be tested by sighting at a plumb-string) it should be made so during this adjustment. This is done by loosening two adjacent screws of the reticule and tapping gently against their heads in the direction required.

Fig. 7.

Fourth, the telescope bubble.—This is generally accomplished by what is called the "peg-adjustment," sometimes also adopted in the adjustment of the engineer's level. Two leveling pegs, *a* and *b*, are driven nearly level and about 250 ft. apart (Fig. 8). The instrument is set up at *A*, about a foot from the rod at *a*, and rod readings are taken at *a* and *b*, these readings being respectively A_a and A_b . Similarly, with the instrument at *B*, readings B_a and B_b are taken. Then, from the nature of the problem,

Fig. 8.

$$A_a - B_a = A_b - B_b \pm 2c \dots \dots \dots (1)$$

in which c = the inclination of the line of sight from the horizontal, between the two rods. Now with the instrument at *B*, fix a point on the rod at *a*, at elevation $B_a \pm c$ above the peg; sight the telescope on this point, using the horizontal cross-hair; and bring the telescope bubble to a level in the tube by raising or lowering one end of the latter, with the adjusting screws. Equation (1), in practice, will determine whether c is + or -. Repeat the above for a new and more refined adjustment.

Fifth, the vertical arc or circle.—If the transit has an attachment for reading vertical angles, it is desirable that the angle shall read zero when the telescope is horizontal. To adjust the vertical arc or circle, level up the instrument, and then level the telescope by the attached bubble. Adjust the vernier (attached to the standards) so the zero mark will coincide with the zero of the vertical circle or arc. If the vernier is not adjustable, record the "index error" to be used with all vertical angles measured.

The Solar Attachment.—This is a small instrument attached to the upper part of the transit telescope, for determining the meridian, latitude, time, etc. It is used largely in government land surveying where the section and township-lines are supposed to run in the direction of the principal points of the compass.

Fig. 9 illustrates the solar apparatus manufactured by the Messrs. Gurley, of Troy, New York.

The circles shown represent those supposed to be drawn upon the concave surface of the heavens. When the telescope is set horizontal by its spirit level, the hour angle will be in the plane of the horizon, the polar axis will point to the zenith,

eros of the vertical arc and its vernier will coincide. If we incline the tube, directed north as shown in the cut, the polar axis will descend from the top of the zenith. The angle through which it moves, being laid off on the arc, will be the co-latitude (90° -latitude) of the place where the instrument

Fig. 9.—Transit with Solar Attachment.

the latitude itself being found by subtracting this angle from 90°. When the sun is above (north of) or below (south of) the equator, its declination, or angular distance above or below, as given in the Ephemeris or Nautical Almanac, can be set off from the declination arc, and its image brought into position as before. In order to find, however, it is necessary not only that the latitude and declination are set off directly upon their respective arcs, but also that the instrument is moved about until the polar axis points to the pole of the heavens, i. e., is placed in the plane of the meridian. Thus the position of the sun's image will indicate not only the declination of the place, the declination of the sun for the given hour, and the time, but it will also determine the meridian, or true north and south line through the place where the observation is made. Allowance for declination—referring to the Ephemeris, and setting off on the arc the declination of the sun for the given day and hour, we are still able to determine its position with certainty as if it remained on the equator. When the sun's declination is from Sept. 22 to Mar. 20) the arc is turned downward, toward the plates of the instrument; during the remainder of the year the arc is turned upward.—From *Nautical Almanac*, page 71, etc.

The Solar Instrument* manufactured by Keut (see Fig. 10), is perhaps one of the neatest and market. Attached to the transit it may be used to find (A) the astronomical meridian, (B) the latitude, and (C) the azimuth. It is also used as a vertical sighting telescope in mining engineering.

Fig. 10.—Solar Instrument.

It consists of a small telescope with prism to eyepiece standard which revolves upon a vertical axis attachable to the transit. This small telescope, called the solar telescope, can be moved in altitude and azimuth, slow motion being imparted to it in tangent screws. The vertical axis, called the polar axis, can be moved with the axis of the earth's rotation by inclining the transit. Attached to the vertical circle giving the inclination. A level is attached to the solar telescope is provided with two pointers, so placed that when one of them falls upon the other, the sun will be in the field of view.

(A). For determining the meridian. (a). Incline the transit telescope until the angle of declination† corrected for refraction, is indicated by the vertical limb or arc, depressing the telescope if the sun's declination is north, and elevating it if it is south. See Fig. 11.

(b). Bring the solar telescope into the vertical plane of the transit telescope, (without disturbing the position of the latter) and also to a horizontal position by means of its level. The two telescopes will now enclose an angle equal to the amount of the declination. See Fig. 12.

(c). Without disturbing the relative positions of the two telescopes, elevate the transit telescope (and with it the solar) until the amount of the co-latitude is indicated by the vernier of the vertical limb. See Fig. 13.

(d). Revolve the two telescopes together upon their respective vertical axes until the image of the sun is brought into the field of the solar telescope; when the sun is accurately bisected the transit telescope will be in the meridian and the compass needle will indicate the amount of its declination at the place of observation. It will of course considerably facilitate this last operation if, before commencing to revolve the two telescopes, the transit one is approximately pointed toward the south by means of the transit compass needle.

(B). For ascertaining the latitude. Direct the transit telescope south, incline it to an amount equal to the sun's meridian declination for refraction, depressing the telescope if the declination is north, and elevating it if it is south. Now bring the solar telescope into the vertical plane of the transit telescope and to a perfectly horizontal position by means of its level. A few minutes before noon (the moment of the sun's culmination) bring the image between the two horizontal wires of the solar telescope. By means of the transit telescope in altitude and azimuth. By means of the transit telescope, keep the sun, as it continues to rise and travel southward, relatively to the cross-hairs of the solar telescope. When it has reached the reading of the vertical arc of the transit, deduct from it the amount of the declination, and the remainder is the co-latitude, which deduces the latitude. The position of the two telescopes is identical. See Fig. 13.

(C). For observing the time. Having brought the two telescopes into the final positions for determining the meridian, that is the transit telescope bisecting the sun, revolve them both upon their vertical axis, without disturbing the vertical axis, until they are both

* Invented by Saegmüller, 1881.

† See American Ephemeris or Nautical Almanac.

by their respective lines of sight, which can be determined by sight—the two telescopes upon any clearly defined distant object, and taking the of the respective readings of the transit horizontal limb, is the hour angle. en reduced to time before or after apparent noon: One degree of arc=4 time and 1 minute of arc=4 seconds of time. The time obtained by observation is reliable to a few seconds.

Adjust the Solar Attachment.—Attach the instrument to a transit adjustment, or adjust the transit as explained, page 942. In nuller solar (Fig. 10) there are two adjustments as follows:

the polar or vertical axis.—Level the transit and also its telescope revolve the solar telescope horizontally about its polar axis whether the bubble in the small tube attached above it moves central position. If so, correct *one-half* the *variation* by the screw *v*, and the other half by adjusting the bubble tube to a level position, sing or lowering one end by the capstan-headed screws. Repeat, bubble remains central when the solar telescope is revolved.

Z, the horizontal hair.—The horizontal lines of sight of the transit and the solar telescope must be parallel with each other. To h this the reticule or diaphragm of the latter is moved upward or d by means of upper and lower capstan-headed screws *s*, Fig. 10, ed in the adjustment of the level.

Observation with Transit Alone.—Mr. A. W. French gives the method* for determining the meridian† from the sun by direct on with the transit and without the use of solar attachment:

serve the sun directly, by the aid of colored glass, and bring his image the horizontal and vertical wires; read the vertical circle and the hori- es. Suppose that in the first pointing the image was approaching the bring it into the opposite quarter of the field of view, where the image m the wires; bring the wires tangent and read as before. The mean of ngs will give the apparent altitude and the plate reading for the sun's the transit has a full vertical circle, the telescope should be reversed e two pointings, to eliminate all errors of adjustment. If the transit has eal arc, no reversal can be made, and great care must be taken that the a and standards are in good adjustment and the index error accurately

d plates when pointing at any convenient mark, thus finding the angle e sun's center and the mark.

putation of the *P Z S* triangle enables us to find the angle between the e north; then, addition or subtraction of the angle between the sun and as the mark is north or south of the sun) gives the angle made by the line mark), and the meridian.

companying form of notes and reductions needs but a few remarks.

OBSERVATION.

Eng. News, May 20, 1897.

meridian is the great circle whose plane passes through the *zenith* es. The *azimuth* of a body is the horizontal arc measured on the between the north point and the vertical circle passing through the s, the azimuth of the sun or of a star in determining the meridian. *ation* of a body is its angular distance from the equator measured r circle; thus the declination of the sun is south in winter, north , and zero when it crosses the equator on March 20 and Sept. 20. e of a body is its distance from the horizon measured on a vertical e *zenith* distance is 90° minus the altitude. "*Co*"—before declina- oogle ide, etc., means the complement of (90° -) these quantities.

ance, or radial distance from pole to star varies from a little more than 1° to a little less than 2° angular measure, varying from day to day, from year to year, and also with the latitude of the place of observation. When the star appears at *E* or *W* (eastern or western elongation, respectively); when it is at its upper or lower culmination. Now if we know the distance of the star when it is at its eastern or western elongation, and also the latitude of the place of observation, it is a very simple matter to find the azimuth of the star or the horizontal angle from the star to the pole, which the surveyor desires in getting the true meridian.

Fig. 14.

$$\text{Azimuth of Star} = \frac{\text{Sine of Polar Distance}}{\text{Cos. of lat. of place of observation}} \dots (1)$$

Table 1, below, is a table of polar distances from latitude 0, the equator, of each 3rd year, 1906–1930; and may be used in connection with formula (1) for any latitude, and for any time (year) by interpolation.

POLAR DISTANCES OF POLARIS FOR LAT. 0, THE EQUATOR.

July 1,		
latitude <i>N</i>	Log sin <i>p. d.</i> for July 1, 1914.....	= 8.30278
30'? Use	Log cos 38°–30' (latitude).....	= 9.89354
and formula	$\therefore p. d. = 1^\circ - 28' - 13''$ Log sin.....	= 8.40924

Polar dist. at elongation of star is called the Azimuth at Elongation. Azimuths +25° to +72°, the direct Azimuths are given in Table 2, on the next page.

Observation of *Polaris* for Azimuth will now be described. The instrument should be in adjustment and be provided with a reflector for illumination of the cross-hairs. This may consist of a circular piece of bright tin of about 1½ inches in diameter of the object glass, and with a hole in it about half its diameter. This annular ring may be fastened to a wire, bent around the

Fig. 15.

the telescope as shown in Fig. 15. It should project outward at an angle of about 45° and the under side may be painted white so as to reflect light from a dark lantern (held beneath it) into the telescope. A bright or illuminated target should be placed several hundred feet from the transit, and about due north to serve in fixing a base line azimuth reading to the star. The target may consist of a vertical strip (about $\frac{1}{16}$ of an inch in width) in a box with a light behind it. (See page 951.)

2.—AZIMUTH OF POLARIS AT ELONGATION JAN. 1.

The azimuth is constantly growing less; hence the yearly decrease.

Ex.—Elongation of Polaris for Lat N(+) 38°—30' during June-July, 1914, or 4½ years after Jan. 1, 1910, is 1°—30' minus 4½ times 0°—0'.40—1°—28'.2.

(a) OBSERVATION OF POLARIS AT ELONGATION.

Before the time of elongation of Polaris, bring the telescope into cutting the star with vertical wire; and with the horizontal angle maintained at zero on the vernier, follow the star by operating the slow-motion screw. When the star ceases to move laterally it has reached its elongation. Now measure the horizontal angle between the star and the target, previously set (p. 949). By working rapidly, the angle may be doubled as a check or for greater accuracy*. Better still, for any error of adjustment of the transit, it may be well to read the angle at 180° for the second reading, with the telescope reversed. Of these two readings will be the correct one to use, and this will be the horizontal angle between Polaris at elongation and the base line fixed by the target. The angle between this base line and the meridian can now be calculated by taking into consideration the hour angle of Polaris at its elongation, for the particular time and latitude, as 1 and 2, and 3†; thus, it will either be equal to the sum or the difference of the hour angle and the azimuth. The operator must have clearly in mind whether the elongation is east or west† and in which direction the angle is taken, in order to lay off the meridian in the right hand. A pencil sketch should be drawn showing the angles.

(b) OBSERVATION OF POLARIS AT ANY HOUR ANGLE.

According to Fig. 14, the hour angle of Polaris (or of any star) is the time elapsed since its upper culmination, at U . The time occupied by making a complete cycle from U to U , is $23^h 56.1^m$, and in half cycle, from U to L or from L to U , is assumed to be one-half of 58^m . Therefore, if we know the time of upper culmination we can subtract or add $11^h 58^m$ to find the preceding or the following lower culmination. To an observer at the equator† (lat. 0), the hour angles of Polaris are: $0^h 0^m$ at U , $5^h 59^m$ at W , $11^h 58.1^m$ at E , and $23^h 56.1^m = 0^h 0^m$ at U again. Now for any point other than the equator the hour angle at western elongation will be diminished, while at eastern elongation it will be increased; the amount of decrease or increase is the lat. of the observer. Thus, in 40° N. latitude the hour angle at western elongation is $5^h 55^m$, and at eastern elongation is $18^h 01^m$, about 4^m in each case from the above as observed at the equator. It will be seen from the above that the azimuth of the star varies with the hour angle and the latitude of the place of observation, as well as the time of observation.

There are two kinds of time which must be kept clearly in mind, viz.,

(c) Time and Astronomical Time. An astronomical day begins at

variation (deduction) of azimuth angle for time of observation or after elongation is very small, being less than $0^\circ - 01'$ for time. The following table shows the relation for lat. 45° N. and for 1910, the azimuth at elongation being about $1^\circ - 40' = 100^\circ$.

Time.	Diff. in Azimuth.	Diff. in Time.	Diff. in Azimuth.
1m	$0^\circ 0.001 = 0.06$	$0^h 25^m$	$0^\circ 0.594 = 35.76$
5	$0 0.024 = 1.4$	$0 30$	$0 0.856 = 51.4$
10	$0 0.095 = 5.8$	$0 32.4$	$0 1. = 60.$
15	$0 0.214 = 12.8$	$0 35$	$0 1.164 = 69.8$
20	$0 0.381 = 22.9$	$0 45.9$	$0 2. = 120.$

In Table 3 we can find whether the elongation is east or west, as in the foot-note accompanying that table.

The difference in time between the upper culmination and the adjacent elongation diminishes with increase in latitude; while the azimuth at elongation increases with increase in latitude.

The variation for longitude is very slight, and for points in the U. S. is negligible for ordinary surveying. Table 3 gives the local mean (astronomical) time of the upper culmination of Polaris, computed for longitude 2^m west of Greenwich. The meridian passes through the mountains (near the edges) of Colorado and New Mexico, and is consequently "central" for U. S. territory. (The eastern edge of Maine is west, the western edge of Oregon about 125° west, and the western edge of Alaska about 168° west.) The error is of course greatest at the times (at which time observation should be avoided when possible) and least at the elongations.

noon of a civil day, and each is 24 hrs. in length. Thus, the A. M. of a civil day corresponds to the last half of the preceding astronomical day, each lapping by 12 hrs.*

In making an observation on Polaris for azimuth, it is necessary to know: (1) the latitude of the place of observation, which may be obtained from a map; (2) the mean local time of observation, which can be calculated from the particular "standard time"† used in that locality when the longitude of the place of observation is known; (3) the horizontal measured angle from Polaris to the previously established base line, explained under (a), preceding, together with the mean local time of observation; (4) the hour angle of Polaris at time of observation, to be calculated from Parts I and II of Table 3; (5) the azimuth of Polaris from the hour angle, date, and latitude of place of observation, to be obtained from Table 4. (6) Find the sum or difference of the azimuth and the measured angle, explained under (a) preceding, and lay it off in the right direction from the established base line.

PRACTICAL EXAMPLE OF USE OF TABLES 3 AND 4.

Place of observation, lat. 41° N., long. 100° W.; Mountain time, 8 30 P. M., Nov. 8, 1911; measured angle from Polaris eastward to base line, $2^{\circ}-40'$. Find the azimuth of Polaris, and the angle of base line with true meridian? Then we have—

	<i>h</i>	<i>m</i>
Standard time of observation (merid. 105° W.).....	8	30.0
For merid. 100° W., add 5×4 m.....		20.0
Mean local time of obs., 1911, Nov. 8.....	8	50.0
Equivalent time to Nov. 7 (add 24 h.).....	32	50.0
	<i>h</i>	<i>m</i>
Astrom. time U. C. Polaris, Nov. 1‡ (Table 3, Part I).....	10	48.0
Reduction to Nov. 7 (Table 3, Part II) Subtract.....	23.6	10 24.4
Hour angle of Polaris at observation.....	22	25.6
Subtract from.....	23	56.1
Time argument for Table 4‡.....	1	30.5
Azimuth of Polaris, at observation (lat. 41°).....	0°	36'.5 E.
Measured angle eastward from Polaris to base line.....	2°	40' E.
Angle of base line eastward from true meridian.....	3°	16'.5 E.
Therefore lay off angle $3^{\circ} 16'.5$ westward from base line to true meridian.		

* Civil time P. M. = astronomical time with the P. M. omitted; thus, 5.30 P. M. = 5h 30m of the same date. Civil time A. M., + 12 hrs. = astronomical time of the preceding date; thus, 5.30 A. M. June 2 = 17h 30m June 1. Astronomical time under 12h = civil time P. M. of the same date; thus 5h 30m = 5.30 P. M. of same date. Astronomical time over 12h, with 12 hrs. deducted from it = civil time A. M. of the following date; thus, 17h 30m June 1 = 5.30 A. M. June 2.

† Standard railway time for longitude west from Greenwich: Intercolonial time, for 60° west, Eastern time, for 75° west; Central time, for 90° west; Mountain time, for 105° west; Pacific time for 120° west. 15° of longitude = 1 hr. of time ($1^{\circ} = 4$ m.); $15'$ of long. = 1 min. of time ($1' = 4$ sec.); $15''$ of long. = 1 sec. of time ($1'' = 0.6\frac{1}{2}$ sec.). Ex.—The place of observation is, say, 108° west, and the observer has Mountain time; hence the mean local time is 3×4 m. = 12 m. *slower* than his watch. For 108° west it would be 12 m. *faster* than his watch. West of standard time meridian means *deduct*; east means *add*.

‡ This is the nearest date preceding, in the table. Values are given in Part I for the 1st and 15th of each month; and in Part II the reduction is given for succeeding dates.

|| Caution.—Be sure to use the same "Diff. for 1 day" in Part II as obtained from Part I, and opposite the day of the month Subtract; don't add.

‡ See "Ex." below Table 3.

MEAN (ASTRONOMICAL) TIME OF THE UPPER CULMINATION OF
 , COMPUTED FOR LONGITUDE 108° (7H. 12M.) WEST OF GREENWICH.
 on line with any date in Part I is the hours and minutes elapsed
 (common watch time) since the preceding noon.]

to find the time of upper culmination of Polaris on Nov. 8, 1911, for longitude of Greenwich?

n.—From Part I of above table we have for Nov. 1, 1911, 10h. 48.0m., and (reduction) for one day is 3.93 m. Now under this diff. in Part II, and in line with the day of the month, 8, in the left-hand column (or in line with the number of days since Nov. 1, namely 7, in the right-hand column) we obtain the total of 27.5m., making the astronomical time of upper culmination 10h. 48.0m. n.—10h. 20.5m., or 10.204 P.M., local civil time. Note that in the practical observation, the actual time of observation was 8.50 P.M. or 1h. 30.5m. earlier.

4.—AZIMUTH OF POLARIS

[The hour angles are expressed in mean solar time. The occurrence of a period after

STAR AND AZIMUTH.
 W. of N. when hour angle is less than $11^h 58^m$.
 E. of N. when hour angle is greater than $11^h 58^m$.
 Time argument, the star's hour angle (or $23^h 56^m .1$ minus the star's hour angle), for the year—

POLARIS above the POLE.
 To determine the true meridian, the azimuth will be laid off to the east when the hour angle is less than $11^h 58^m$, and to the west when greater than $11^h 58^m$.

Note.—From the "Ex." below Table 3, preceding page, we find that the upper culmination of Polaris occurs at 10.20 P. M. on Nov. 8, 1914; and that the time of observation is fixed at 8.50 P. M., mean local time, or 1 h. 30.5 m. earlier. Hence the position of Polaris at the time of observation is just to the right of U, Fig. 14, p. 949. Moreover, the star's hour angle at observation is $23^h 56^m .1$ minus 1 h. 30.5 m. = $22^h 25^m .6$, which corresponds with that given in the practical example preceding. Have graphically in mind the position of the star, and its apparent motion, and the calculations become simple.

LAND SURVEYORS.

e or of an hour angle indicates that its value is 0°. 5 greater than printed.]

R AND AZIMUTH.

hour angle is less than

hour angle is greater than

at, the star's hour angle (or
as the star's hour angle),

POLARIS below THE POLE.

To determine the true meridian, the azimuth will be laid off to the east when the hour angle is less than 11^h 58^m, and to the west when greater than 11^h 58^m.

—The time of lower culmination of Polaris occurs 11h. 54m. before or after the upper culmination. The time of eastern and of western elongation occurs lately 5h. 55m. before and after the time of upper culmination. Hence the elongation may be obtained from the above table. See also Fig. 14, p. 949, and p. 950, for data in this connection.

Tapes.—The best form of tape for general surveying is a 100-ft. steel ribbon with graduations to feet, tenths, and hundredths. The zero end of the tape should be *the end of the steel ribbon itself*, and it may be provided with a small handle or a large detachable handle, the latter for continuous line measurements. The 100-ft. end should also be provided with detachable handle so it can be wound in a box.

Every city surveyor should keep, in his office, a standard tape tested by the U. S. Coast and Geodetic Dept. at Washington, and certified to as correct at a certain *standard temperature*, say 60° F., and for a certain pull, say 10 to 15 lbs., when uniformly supported. This should be used as a test tape only, and never for field work. The advantage of such a standard over a fixed base (as on a pavement) is that the temperature* of the tapes need not be taken during the test. Nor is it necessary to use the spring balance, as the tapes can be brought to practically the *same* tension without it. It is necessary of course to use the same pull for the field measurements and this is one of the tricks of chaining.† The "misuse" of the thermometer in the field is often a source of "error." That is to say, the temperature of the thermometer will never indicate the temperature of the tape, exactly. Both will be affected differently by the sun's rays, surrounding air, wind and temperature of ground. The best chaining is done on cloudy days and in still air.

Temperature corrections should be *added* to a *measured length* between two *fixed points* in the field when the temperature of the tape is *above* the *standard temperature*; *subtracted* when *below*. Reverse the above when *laying out* a fixed distance, as setting one point from another.

5.—TEMPERATURE CORRECTIONS IN FEET PER 100 FEET.

Note.—Use signs as per table for measurements between fixed objects. Reverse signs in table when laying out fixed distances.

(From the author's "Railway Right-of-Way Surveying." ‡)

* The tapes should lie unwound in the same atmosphere for some little time before making the test.

† On very accurate city work it is often desirable to let the chainmen use the spring balance until they get accustomed to the proper tension, after which it may be discarded generally, or used only occasionally to keep them in tune.

‡ Published by McGraw-Hill Book Company, New York.

and the Stretch of a Tape supported at two or three points, positions 2 and 3, may be made to equalize each other, by applying equal tension or pull at the ends, so that the horizontal measured remain the same, and equal also to the length of the tape when throughout as in position 1. Practical advantage is taken of the in measuring with a single- or double-sagged tape. The pull P_1 , for is of course fixed when the tape is standardized, while P_2 and P_3 , s 2 and 3, are obtained with the spring balance and by plumbing ed points a and b . If it is desired, however, to maintain a constant for all three positions of the tape (and this is generally the

Fig. 16.

mod) then the horizontal distance error must be determined and r positions 2 and 3. These "distance errors" will become the ors or "sag" errors of the tape, and are to be used in addition perature" corrections. Care must be used in maintaining the d tension while measuring, as a difference of 6 lbs. in pull, when uniformly supported, will affect an ordinary 100-ft. steel tape 0.01 he exact amount depends upon the size (area) of the ribbon, and s of elasticity of the steel. It can best be determined with the tape, using the spring balance and watching the amount of he apparent stretch of a sagged tape is greater than when lying differ very much in area, varying from about .0015 to .008 sq.

ngineer's Chain (100 1-ft. links) is recommended for rough work inous or lava country, but it is often used where the steel (ribbon) prove more expeditious. rveyor's or Gunter's Chain (100 7.92-in. links), 66 ft. long, is y in the West in connection with government land surveys. useful in retracing old land surveys made before the engineer's a came into use.

6.—TABLE OF FEET AND CHAINS (GUNTER'S OR SURVEYOR'S).

(1 chain = 100 links; 1 link = 7.92 ins.)

(b) Feet to Chains.

Feet.	Chains.	Feet.	Chains.	Feet.	Chains.	Feet.	Chains.	Feet.	Chains.
1	.015 ¹⁵	3	.045 ⁴⁵	5	.075 ⁷⁵	7	.105 ⁰⁶	9	.135 ³⁶
2	.030 ³⁰	4	.060 ⁶⁰	6	.090 ⁹⁰	8	.121 ²¹	10	.151 ⁵¹

Note.—The inverted caret indicates repeating decimal; thus, 1 ft. = 0.015 15 15 15 ——— chain.

Ex.—Reduce 18 ch. 45 l. to feet?

Solution:

18 ch = 11.88 ft. ∴ 18 ch = 1188.00ft.

45 ch = 29.70 ft. ∴ 45 l. = 29.70ft.

Ans. 18 ch 45 l. = 1217.70ft.

Or, mult. 18.45 by 66.

Ex.—Reduce 482.73 ft. to ch. and l.

Solution:

400ft. = 6.0606ch. .70ft. = .0106 ch.

80ft. = 1.2121ch. .08ft. = .0003 ch.

2ft. = 0.0303ch.

Ans. 7 ch. 31.41 l.

Or, divide 482.73 by 6 and 11.

Methods of Platting Angles.—There are three principal methods of platting angles:

By the Protractor. The cheapest, simplest and perhaps most generally for general use is the paper protractor, a complete circle 14 ins. in diameter graduated to $\frac{1}{4}$ degrees. Steel and German silver protractors with sliding arms and verniers are convenient but expensive, costing from \$40.00 and upward, while the large paper protractor may be had for about 30 cts.

By Tangents. This consists of laying off by the use of the Table of Natural Tangents (p. 144.) Thus, in Fig. 17, let it be required to lay off the angle $\alpha = 28^\circ - 16'$ from the Base.

Lay off a length of Base, to any scale, some multiple of 10, say 1000; then the length of Altitude, at right angles to the Base, will equal 1000 mult. by $\tan \alpha = 1000 \times 0.5377 = 537.7$ on the same scale. Draw the Hypotenuse, which now makes the required angle with the Base. This method is desirable for small angles. For very long lines, the method of Chords is often preferred.

By Chords. Assume a length of Base as some multiple of 10, say 1000. With a radius of 1000 describe the arc ab , Fig. 18. In the following Table of Chords to Radius 1 find the chord corresponding to the angle α , assumed here $\alpha = 28^\circ - 16'$. This value, 0.4884, mult. by 1000, the radius, = 488.4 the desired Chord, or radius with center at a , to intersect at b . Draw Ob ; this is the desired angle α . Note that the length of the Chord (i.e., radius of circle), mult. by twice the angle α does not exceed 90° .

Fig. 17.

Farm Surveying.—Let it be required to make a survey of a farm of about 150 acres, locating the roads, fences, buildings, determining the acreage, and making the map. As the farm is, say, about 30 miles from the city the surveyor decides that he will prepare to spend one day in the field, only.

The Equipment consists of 1 transit, 2 100-ft. tapes, 2 flag poles (Fig. 19), 12 pins (Fig. 20) with red flannel tied at their tops to prevent losing them, 1 axe, 1 hatchet, 1 transit plumbbob (Fig. 21), 1 plumbbob (Fig. 22) for each of the men, 1 steel frost pin (Fig. 23) if the ground is frozen, and the stakes (Fig. 24),

Fig. 21. Fig. 22. Fig. 23. Fig. 24. Fig. 25.

hubs (Fig. 25), tacks, etc. (The stakes may perhaps be procured on the ground, but it is often cheaper to take them from the office.) Four men, say, besides the chief of party, comprise the working outfit.

The Traverse of the farm is represented (Fig. 26) by the broken instrument-line $A B C D E A$, which closely follows the fence lines (not shown). In running around the farm with this traverse, lettered or numbered stakes are set on the instrument lines opposite all bends in the fence lines; these stakes are located by base line measurements, and from them the offset distances are measured to the fences, thus completely tying-in the farm boundary. Any building as H may be located by running a spur instrument line from some point on the traverse, as B . The traverse itself is determined by the lengths of the measured base lines, $A B$, $B C$, $C D$, etc., and by the measured angles at A , B , C , etc. *Inaccuracies* in measurement, both in base line distances and in angles, will usually creep into the work and hence the traverse will seldom *close*, that is, it will have to be *adjusted*. Absolute *errors*, however, can be eliminated by measuring the base lines twice and by "repeating" all angles, and these should be examined carefully before leaving the field.

Fig. 26.

The Adjustment of the Traverse may be made in several ways, but the simplest and most practical is as follows: Let A , B , C , etc., be the interior angles, measured in the field, at the respective corners of the traverse (Fig. 26). The sum of these angles should equal 540° ($=180^\circ \times$ number of sides $- 360^\circ$) if there is perfect accuracy in the field work. If the angles add up to within a few minutes of 540° this variation may be proportioned among all the angles so their sum will equal 540° . But greater weight should be given to those measured angles with the (longest and) *clearest* foresights, as A , especially if the angle "doubled" accurately when measured in the field; and less weight should be given to, say, C and D , especially if the angles did not "double" or "repeat" properly. Having adjusted the angles (Fig. 27) so their sum is 540° , assume one side of the traverse as a base line, say $A B$, and cut the exterior of the traverse into right angle triangles as shown by the dotted lines; calculate the angles a , c_1 , c_2 and e , from the

Fig. 27.

sted interior angles A, B , etc.; solve the sides of the triangles, using measured base lines of the traverse, in each case, as the hypotenuse connection with the calculated angles a, c_1 , etc.
The final test is now made by adding together the horizontal distances of the top of the traverse, which we will call W , and comparing with the of the horizontal distance at the bottom, which we will call E ; like the sum of the right-hand vertical distances N should "equal" the left-vertical distances S . If there has been no radical error in the field, they should check fairly well; thus, Fig. 27, starting from A , we have,

(+) E	(+) N	(-) W	(-) S
2977.69	+ 1187.06	- 458.60	- 2387.76
694.70	+ 917.47	- 2211.39	
	+ 283.61	- 1001.88	
3672.39	+ 2388.14	- 3671.87	- 2387.76
3671.87	- 2387.76		

0.52 and + 0.38 = closing errors. (See Fig. 28.)
to "close" the traverse, construct a closing diagram as per Fig. 29, off the base line measurements AB, BC , etc., consecutively and sufficient accuracy, from Fig. 27. At the right-hand end, at A , lay off closing errors, 0.38, 0.52 and the hypotenuse or closing line 0.64,

Fig. 28.—Adjusted Traverse.

ly above the base line AA , and draw rays to A , intersecting verticals from B, C, D and E . The scaled distances from the base line to intersections will be the closing errors to be used at these points, B, C, D and E , in Fig. 28, the closing line at each point being parallel to the line shown dotted at A , and the errors at any point being proportional to the total distance on the base line from the initial point A , in the

Fig. 29.—Closing Diagram.

a of the lettering. Fig. 28 need not be drawn to scale, the adjusted being shown by full lines and the unadjusted traverse (greatly enlarged by using an enlarged scale for the closing errors) being shown by dotted lines. Now construct external triangles around the adjusted lines, calculate their sides (applying difference in errors obtained in Fig. 28 to the calculated sides in Fig. 27) and their angles. From the angles, calculate, by addition and subtraction, the new interior angles of the adjusted traverse. All calculations should be made in regular calculation books (unruled pages), numbered and indexed. Cross-sections are always desirable for field books, calculation books and office

The Office Plan is made on heavy manila detail paper. The adjusted traverse is shown in red ink. Angle points on the instrument lines are indicated by being enclosed in a small triangle; and ordinary hubs, at other points, by a small circle. The property lines are in black (India) ink, as are also the outlines of buildings. Lanes may be indicated by parallel dotted black lines, and streets by full shaded lines. Fences may be shown by fine black lines (unless they mark the property boundary) and should be lettered "*Fence*," "*Stone wall*," etc.; or they may be indicated by broken lines as for instance alternate dashes and dots. All corrected measurements and angles are given on the office plan as they appear in the field book or calculation book, and cross reference is made to each other. The lettering is slanting, and is made by single strokes of the pen, including names of streets, buildings, etc. All information should be recorded, including the acreage of the property. This is usually obtained by calculating the area of the traverse and making the necessary additions and subtractions when the boundary line of the property is respectively exterior or interior to the traverse lines. Field measurements are taken in such a way as to simplify office calculations. Both magnetic and true north are shown. The title is preferably in the lower right-hand corner and should include the name of the property (owner), location, date of survey and by whom, reference to field book, date of plan, and scale. The author has found it convenient to cut out a small 45° triangle from the lower right-hand corner of the plan so that when the plans are lying in the case drawer, the thumb can be inserted and the number of the plan sought can be seen readily. The plan numbers are adjacent to the corners so cut.

The Finished Map which is furnished to the owner of the property is on mounted white paper with rough surface. Paragon paper or its equal is recommended. The transfer is made with the steel or needle point from the office plan. All instrument lines are omitted, but the property lines are shown with distances and angles just as though the instrument lines had actually traced them and they were the real traverse. In other words, the property line traverse should contain sufficient data so it can be plotted to "close," and also be described in deed. All lines should be in India ink. The slant-block lettering, plain or fancy, is easy to make, neat, and clean. The upright Roman lettering for street names is perhaps more desirable than the block lettering, but requires greater care in proportioning and execution. The title should be in taste with the general map, neat and compact. It should always include the scale, date, and surveyor's name. It is a mistake to color a map too highly. The property boundary may be shaded with a diluted carmine, and the streets tinted with burnt sienna. Buildings may be tinted with the proper colors* to represent wood, brick, stone, etc. The north point should be neat and artistic but not coarse. It should be placed in a position to "balance" the map. The border may consist of a heavily leaded line between two finer lines; or one of the latter may be omitted. The corners are generally made as in Fig. 30, but may be curved to various patterns.

Fig. 30.

City-Lot Surveying.—The functions of the surveyor are almost judicial in character. No statutes are framed or can be framed to meet all cases of conflicting deed lines. These conflicts arise from inaccurate surveys in the past when land was cheap, and also from improper wording of deeds of conveyance. The inaccurate surveys were due in part to the use of chains which were longer or shorter than the present standard. This is the cause of much of the "surplus" and "deficiency" existing in many of our city blocks, amounting in some cases to several inches per hundred feet. Jersey City, N. J., is a notable example of surplus, some of the blocks being 4 ins. per 100 ft. too long. The sensible way is to distribute this surplus proportionately or, in other words, to *use the same length of chain by which the blocks were laid out originally*. But this cannot be held to in all cases because

* Technical or conventional colors may be purchased in liquid form (25 cts. per bottle) in the following colors: 1 cast iron, 2 wrought iron, 3 steel, 4 copper, 5 brass, 6 machinery, 7 leather, 8 light wood, 9 dark wood, 10 brick, 11 stone, 12 brown stone, 13 Prussian blue, 14 gamboge, 15 yellow ochre, 16 vermilion, 17 burnt sienna, 18 carmine. The same may be purchased in water colors (10 cts. per half pan) with the exception that Chinese white is substituted for burnt sienna (17). Digitized by Google

he lines have been established by mutual consent, expressed or Perhaps one or more buildings have been erected and have absorbed not quite all the surplus in the block. If on the other hand there is a deficiency of total measurement, we have a more serious problem to solve.

Those having the prior deeds are apt to oppose any proportionate adjustment of the "deficiency," throwing it entirely in the last lot contained in the block. Existing buildings have much to do with the solution of these problems.

The purpose of the surveyor is to adjust the deficiencies or losses as equally as possible without injustice to no one. It is well to remember that in making out deeds of original survey the description of each lot is referred to the same street line.

Fig. 31, the west line of 1st St. may be used as the initial base of all lots in block. The width of lot 8 should read "25 ft. less" to the east line of 2nd St.

lot lines in small cities should be fixed by stone monuments set on the corners at the street intersections. As the cities grow in size these monuments are bound to be disturbed, but they have served their purpose well for ready use. Offsets to buildings may now be used or the monument points transferred to the manholes* which have supplanted the monuments. The point selected on the building should be such as will be best described, as *above or below the water table*; the corner of a building is the best, as being definite. Where sewers, water works and other lines have been introduced more rapidly than substantial buildings have been erected, it is quite customary to transfer the stone monuments to the centers to the corners of the streets, say on 2-ft. to 10-ft. centers.

Fig. 31.

Government Land Surveying.—The following is a digest of General Land Office "Circular on Restoration of Lost and Obliterated Corners and Division of Sections," Revision of June 1, 1909.

"An obliterated" corner is one where no visible evidence remains of the original surveyor in establishing it; but it is not a "lost" corner if the location has been preserved beyond all question by acts of landowners, and by the memory of those who knew and recollect the true situs of the original monument.

SYNOPSIS OF ACTS OF CONGRESS.

ACT OF MARCH 3, 1785. Prescribing mode of survey for the "Western Territory, said territory to be divided into "townships of six miles square, by running lines due N and S and others crossing them at right angles," as near as may be. Further provided that the first line running N and S should be on the Ohio river, at a point due to the western terminus of a line run as the south boundary of the State of Ohio, and the first line running E and W should begin at the same point and extend through the whole territory. In these initial surveys only the exterior lines of the townships were surveyed, but the plats were marked by subdivisions into sections of 36 square miles, numbered from 1 to 36, commencing with No. 1 in the southeast corner of the township, and running from S to N in each tier to No. 36 in the northwest corner of the township; mile corners were established on the township lines. The territory embraced what is known as the "Seven Ranges" in Ohio.

ACT OF MAY 18, 1796. "Territory northwest of the River Ohio, and above the mouth of the Kentucky River." Section 2 provided for dividing lands "by N and S lines according to the true meridian, and by others crossing them at right angles, so as to form townships of 6 miles square," etc. Also that "one-half of said townships, taken alternately, should be subdivided into sections containing, as nearly as possible, 640 acres each, by running through the same each way parallel lines at the distance of every two miles; and by marking a corner on each of said lines at the end of every two miles." Also that "the sections shall be numbered, respectively, beginning with No. 1 in the northeast section, and proceeding west and east alternately through the township, with progressive numbers till the 36th is completed."

ACT OF MAY 10, 1800. Amendatory to the foregoing. "Townships west of the Muskingum River, which are directed to be sold in quarter townships, to be subdivided into half sections of 320 acres each, as nearly as may be, by running parallel lines through the township from E to W, and from S to N, at a distance of one mile from each other, and

* Four marks with a cold chisel on the fixed iron rim and at quadrant points will determine the true center.

† This method of numbering sections is still in use.

marking corners, at the distance of each half mile on the lines running from *E* to *W*, and at the distance of each mile on those running from *S* to *N*. And the interior lines of townships intersected by the Muskingum, and of all townships lying east of that river, which have not heretofore been actually subdivided into sections, shall also be run and marked — — —. And in all cases where the exterior lines of the township thus to be subdivided into sections or half-sections, shall exceed or shall not extend six miles, the excess or deficiency shall be specially noted, and added to or deducted from the western or northern ranges of sections or half-sections in such townships, according as the error may be in running the lines from *E* to *W* or from *S* to *N*."

JUNE 1, 1796. Act "regulating the grants of land appropriated for military services, etc., provided for dividing the "U. S. Military Tract," in Ohio, into townships 5 miles square, each to be subdivided in quarter townships containing 400 acres.

MARCH 1, 1800. Amendatory of the foregoing act. Section 6 enacted that the Secretary of the Treasury was authorised to subdivide the quarter townships into lots of 100 acres, bounded as nearly as practicable by parallel lines 160 perches in length by 100 perches in width. [1 perch = 1 rod = 16.5 ft. = $\frac{1}{4}$ chain.] These subdivisions into lots were made upon the plats in the office of the Secretary of the Treasury and did not agree with the actual survey made later, many fractional lots being entirely crowded out. This fact may explain some of the difficulties met with in the district thus subdivided.

FEBRUARY 11, 1805. This act directs the subdivision of land into quarter sections, and provides that all corners marked in the field shall be established as the proper corners of the sections or quarter sections which they were intended to designate, and that corners of half and quarter sections not marked shall be placed as nearly as possible "equidistant from those two corners which stand on the same line." Also that "the boundary line actually run and marked [in the field] shall be established as the proper boundary lines of the sections, or subdivisions, for which they were intended, and the length of such lines as returned by either of the surveyors aforesaid shall be held and considered as the true length thereof and the boundary lines which shall not have been actually run and marked as aforesaid shall be ascertained by running straight lines from the established corners to the opposite corresponding corners, but in those portions of the fractional townships where no such opposite or corresponding corners have been or can be fixed, the said boundary lines shall be ascertained by running from the established corners due *N* and *S*, or *E* and *W* lines, as the case may be, to the water course, Indian boundary line, or other external boundary of such fractional township."

APRIL 24, 1820. This act provides for the sale of public lands in half-quarter sections, and requires that "in every case of the division of a quarter section the line for the division thereof shall run *N* and *S*, — — — and fractional sections, containing 160 acres and upward, shall in like manner, as nearly as practicable, be subdivided into half-quarter sections, under such rules and regulations as may be prescribed by the Secretary of the Treasury; but fractional sections containing less than 160 acres shall not be divided."

MAY 24, 1824. This act provides "that whenever, in the opinion of the President of the U. S., a departure from the ordinary mode of surveying land on any river, lake, bayou or water course would promote the public interest, he may direct the surveyor-general in whose district such land is situated, and where the change is intended to be made, under such rules and regulations as the President may prescribe, to cause the lands thus situated to be surveyed in tracts of two acres in width, fronting on any river, bayou, lake, or water course, and running back the depth of forty acres."

APRIL 5, 1832. This act directed the subdivision of the public lands into quarter-quarter sections; that in every case of the division of a half-quarter section the dividing line should run *E* and *W*, and that fractional sections should be subdivided, under rules and regulations prescribed by the Secretary of the Treasury. Under this provision the Secretary directed that fractional sections containing less than 160 acres, or the residuary portion of a fractional section, after the subdivision into as many quarter-quarter sections as it is susceptible of, may be subdivided into lots, each containing the quantity of a quarter-quarter section as nearly as practicable, by so laying down the line of subdivision that they shall be 20 chains wide, which distances are to be marked on the plat of subdivision, as are also the areas of the quarter-quarters and residuary fractions.

These two last acts provided that the corners and contents of half-quarter and quarter-quarter sections should be ascertained as nearly as possible in the manner and on the principles prescribed in the act of February 11, 1805.

GENERAL RULES FROM THE FOREGOING ACTS.

1st. Boundaries established and returned by the duly appointed Government surveyors, when approved by the surveyor general and accepted by the government, are unchangeable.

2nd. Original township, section, and quarter-section corners established by the Government surveyors must stand as the true corners which they were intended to represent, whether the corners be in place or not.

That quarter-quarter corners not established by the Government surveyors placed on a straight line joining the section and quarter-section corners and between them, except on the last half-mile of section lines closing on the west boundaries of the township, or on other lines between fractional

That all subdivisional lines of a section running between corners established in a survey of a township must be straight lines, running from the proper section line to its opposite corresponding corner in the opposite section

That in a fractional section where no opposite corresponding corner has been established, any required subdivision line of such section must be run from the proper original corner in the boundary line due *E* and *W*, or *N* and *S*, as may be, to the water course, Indian reservation, or other boundary of such section due parallelism to sectional lines.

Extinct corners of the Government surveys must be restored to their original locations, whenever it is possible to do so; and hence resort should always be had to the marks of the survey in the field. The locus of the missing corner must be identified on the ground by the aid of the mound, pits, line trees, trees, etc., described in the original survey, as their identification affords the means of relocating the missing corner in its original position. Next to this, the most convincing testimony of citizens as to the locality it originally occupied should be taken, if such can be obtained. In any case, whether the locus of the corner is fixed by the one means or the other, such locus should always be tested and confirmed by measurements to *known* corners.

Special cases may be noted as follows: (a) When new measurements are made on a single line to determine the position thereon for a restored lost corner or corner on a section line), or when new measurements are made between corners on two lines for the purpose of fixing by their intersection the position of a restored missing corner (as a corner common to 4 sections or townships), the measurements, using the original field notes, must be used, recognizing errors in the original chaining. (b) When the relocated corner cannot be harmonized with the field notes in all directions it sometimes becomes the duty of the surveyor to place it according to the requirements of one line and against another line. For instance, if the line between sections 30 and 31, reported as being in length [2 chains short,] would draw the missing corner on range line 12 westward out of range with the other exterior corners, the presumption is strong that the range line had been run straight and the length of the section line wrongly reported, because experience shows that west range lines are less important than range lines and more liable to error. (c) Again, if a corner on a standard parallel has been obliterated, it is proper to assume its position placed in line with other corners, and if an anomalous length of line reported between sections 3 and 4 would throw the closing corner into the northern township, the surveyor would properly assume that the older survey of the standard line is correct in the length of the later and minor line. The marks or corners found on the standard parallel, at which point the lost closing corner may be placed, must conform to the rule of the law that "all corners marked in the field shall be established at the points which they were intended to designate," and the further rule that "if any of the lines returned by the surveyors shall be held and considered as the true lines thereof," are found in some cases to be impossible of fulfillment in all cases. At once, and discretion must be applied by the surveyor. (e) In a case of an old but existing closing corner, which was set some distance out of the true boundary of Missouri and Kansas, it was held by this office that a surveyor of the fractional section should preserve the boundary as a straight line, and not regard said closing corner as a proper corner of the adjacent fractional section. Said corner was considered as fixing the position of the line between two sections, but that its length extended to a new corner to be set on the new line. (f) The principle of the preponderance of one line over another of equal importance has been recognized in the rule for restoring a section corner common to two townships. The new corner should be placed on the township line; and attempts to check its position by distances to corners within the townships are not to be made, if it is found to agree well, but should not cause it to be placed off the township line, if it does not agree, if the general condition of the boundary supports the presumption that it was properly aligned.

TO RESTORE LOST OR OBLITERATED CORNERS.

How to restore corners on base lines and standard parallels.—By proportionate measurements on the line, using original field notes and joining the nearest identified standard corners on opposite sides of missing corner or corners. (a) "Standard" means standard township, section, quarter-section, and meander corners; closing corners as are used in the original survey to determine the position of the standard parallel, or established during the survey of the same. (b) A lost or closing corner from which a standard parallel has been initiated or to which it has been directed will be reestablished in its original place by proportionate

measurement from the corners used in the original survey to determine its position; measurements from corners on the opposite side of the parallel will not control. (c) A missing closing corner originally established during the survey of a standard parallel as a corner from which to project surveys south will be restored to its original position by considering it a standard corner and treating it accordingly. (d) Therefore, from the preceding, using proportionate measurements, we have: "As the original field-note distance between the selected known corners is to the new measure of said distance, so is the original field-note length of any part of the line to the required new measure thereof." (e) As existing original corners must not be disturbed, discrepancies between the new and the original field-note measurements of the line joining the selected original corners will not affect measurements beyond said corners. Proportionate measurements are to be used between them. (f) After having checked each new location by measurement to the nearest known corners, new corners will be established permanently and new bearings and measurements taken to prominent objects, and recorded for future reference.

2. *Restoration of township corners common to four townships*.—Two cases: 1st. Where the position of the original corner has been made to depend upon measurements on two lines at right angles to each other: A line will first be run connecting the nearest identified original corners on the meridional township lines, north and south of the missing corner, and a temporary corner will be placed at the proper proportionate distance, thus determining the corner in a north and south direction only. Next, the nearest original corners on the latitudinal township lines will be connected and a point thereon determined in a similar manner, near the intersection with the meridional line just run. The intersection of these two lines will define the position for establishing the true corner. 2nd.—Where the original corner has been located by measurements on one line only; for example, as a guide meridian: Restoration of corner is effected by proportionate measurements on said line, as previously explained.

3. *Reestablishment of corners common to two townships*.—The two nearest known corners on the township line (the same not being a base or a correction line) to be corrected as in case No. 1, by a right line, and the missing corner established by proportionate distance, and to be "checked" upon by measurements laterally to nearest known section or quarter-section corners.

4. *Reestablishment of closing corners*.—Measure from the quarter-section, section, or township corner east or west, as the case may be, to the next preceding or succeeding corner in the order of original establishment, and reestablish the missing corner by proportionate measurement.

5. *Reestablishment of interior section corners*.—Same manner as corners common to four townships. When a number of corners are missing on all sides of the one sought to be reestablished, the entire distance must be measured between the nearest existing recognized corners both N and S, and E and W, in accordance with the rule laid down, and the new corner reestablished by proportionate measurement.

6. *Reestablishment of quarter-section corners on township boundaries*.—Only one set of quarter-section corners are actually marked in the field on township lines, and they are established when the township exteriors are run. When double section corners are found, the quarter-section corners are considered generally as standing midway between the corners of their respective sections, and when required to be established or reestablished, they should generally be so placed.

7. *Reestablishment of quarter-section corners on closing section lines between fractional sections*.—Must be reestablished according to the original measurement of 40 chains from the last interior section corner, or rather that distance corrected by proportional measurement of original field notes and the new measurement on closing line.

8. *Reestablishment of interior quarter-section corners*.—The missing quarter-corner (in the later surveys) must be established equidistant between the section corners marking the line, according to the field notes of the original survey.

9. *Where double corners were originally established, one of which is standing, to reestablish the other*.—It being remembered that the corners established when the exterior township lines were run, belong to the sections in the townships north and west of those lines, the surveyor must first determine beyond a doubt to which sections the existing corner belongs. This may be done by testing the corners and distances to witness trees or other objects noted in the original field notes of the survey, and by remeasuring distances to known corners. Having determined to which township the existing corner belongs, the missing corner may be reestablished in line north or south of the existing, as the case may be, at the distance stated in the field notes of the original survey, by proportionate measurement, and tested by retracement to the opposite corresponding corner of the section to which the missing corner belongs.

SUBDIVISION OF SECTIONS.

1. *Subdivision of sections into quarter sections*.—Run straight lines from the established quarter-section corners, U. S. surveys, to the opposite corresponding corners. The point of intersection of these lines will be the legal center of the section. (a) Upon the lines closing on the north and west boundaries of a township, the

section corners are established by the U. S. deputy surveyors, but in such sections said quarter-corners should be so placed as to suit the calculation of the areas of the quarter sections adjoining the township boundaries as shown upon the official plat, adopting proportionate measurements where the measurements of the north and west boundaries of the section differ from the measurements.

Subdivision of fractional sections.—Where opposite corresponding corners have or cannot be fixed, the subdivision lines should be ascertained by running established corners due N, S, E or W, as the case may be, to the water course, boundary line, or other boundary of such fractional section. (a) The law requires the section lines surveyed and marked in the field by the U. S. deputy surveyors due N and S or E and W lines, but in actual experience this is not always done.

Hence, in order to carry out the spirit of the law, it will be necessary in such fractional sections to adopt mean courses for the subdivision lines through fractional sections to adopt mean courses for the section lines are not due lines, or to run the subdivision line parallel to the N, or S, or E, or W, or N boundary of the section, as conditions may require, where there is no other sectional line.

Subdivision of quarter sections into quarter-quarters.—Preliminary to the subdivision of quarter sections, the quarter-quarter corners will be established at points between the section and quarter-section corners, and between quarter corners and the center of the section, except on the last half mile of the lines closing on the east or west boundaries of a township, where they should be placed at 20 chains, or at the nearest measurement, to the north or west of the quarter-section corner. The quarter-quarter section corners having been established as directed, the subdivision lines of the quarter section will be run straight between corresponding quarter-quarter section corners on the quarter-section lines. The intersection of the lines thus run will determine the place for the common corner to the four quarter-quarter sections.

Subdivision of fractional quarter sections.—The subdivision lines of fractional quarter sections will be run from properly established quarter-quarter section corners due N, S, E or W, to the lake, water course, or reservation which renders the section fractional, or parallel to the east, south, west, or north boundary of the section, as conditions may require. (See par. 2 (a).)

Proportionate measurement.—By "proportionate measurement" is meant a measurement having the same ratio to that recorded in the original field notes as the length of chain used in the new measurement has to the length of chain used in the original survey, assuming that the original and new measurements have been made. For example: the length of the line from the quarter-section corner to the east side of sec. 2, T. 24 N., R. 14 E., Wisconsin, to the north line of the township, as reported by the United States deputy surveyor's chain, was reported as 45.40 chains; the county surveyor's measure is reported as 42.90 chains; then the distance to the quarter-quarter section corner should be located north of the quarter-quarter corner would be determined as follows: As 45.40 chains, the Government's measure of the whole distance, is to 42.90 chains, the county surveyor's measure of distance, so is 20.00 chains, original measurement, to 18.90 chains by the surveyor's measure, showing that by proportionate measurement in this case the quarter-quarter section corner should be set at 18.90 chains north of the quarter-quarter corner, instead of 20.00 chains north of such corner, as represented on the plat. In this manner the discrepancies between original and new measurements are equitably distributed.

USEFUL TABLES IN PUBLIC LANDS SURVEYS.

(From the Manual of 1902.)

The system of rectangular surveying, authorized by law May 20, 1785 (1 Stat. 237), was first employed in the survey of U. S. public lands in the State of Ohio.

The boundary line between the States of Penn. and Ohio, known as "Mingo line," in longitude 80° 32' 20" west from Greenwich, is the line to which the first surveys are referred. The townships east of this line, in Ohio, are numbered from south to north, commencing with No. 1 on the Ohio River, while the ranges are numbered from east to west, beginning with No. 1 on the east boundary of the State, except in the designated "U. S. Military Land," in which the townships and ranges are numbered, respectively, from the south and east boundaries of said tract. In 1875, numbered and locally-named principal meridians and base lines have been established as shown by Table 8, following.

8.—MERIDIANS AND BASE LINES OF UNITED STATES SURVEYS.

Principal Meridians.	Governing surveys (wholly or in part) in States of—	Longitude W. from Greenwich.	Runs near—	Base line.	Latitude N.	Runs near or with—

10	23½	20	46½	30	70	40	93½	50	116½	60	140

Remarks.—Table 12, showing the departure or falling at 80 chains distance, for any number of minutes up to 60, can also be used in finding the minutes of correction of a random course corresponding to the number of links of falling. For distance less than 1 mile, the links of falling must be proportionately increased; for example, if the falling at 70 chains is 28 links, the correction of the course will be 14 minutes for 32 links. For township exteriors and other long lines, the number of links of falling must be divided by the number of miles to bring the calculation to the basis of the table.

Table 12 may be used to determine the return from the random course, also, by keeping in mind clearly just what is being done.

CONVERGENCY OF MERIDIANS SIX MILES LONG AND SIX MILES APART, AND OTHER RELEVANT DATA, TO LATITUDE 70° NORTH.

REMARKS ON TABLE 13.

second column of Table 13 contains the convergency of two meridians six miles long and six miles apart, measured on a parallel of latitude.

When the parallel of latitude passing through the south end of the meridians, and forming the south boundary of the township of which the meridians form the meridional boundaries, is coincident with a tabular latitude given in the first column, the required convergency will be obtained directly from the second column (see Fig. 34); while for other than tabular latitudes, it will be obtained by simple proportion (Fig. 35). The third column contains the angle of convergency. (abc, Figs. 34 and 35.) For the purpose of computing convergency within the boundaries of a township, said boundaries may be regarded as straight lines and the tract as a plane figure, generally a trapezoid; the convergency of any meridian part thereof, bounded by meridional and latitudinal sections will be determined as follows: Multiply the convergency for the tract, determined as above directed, by the length of the tract in miles

and decimals of a mile, divided by 6, and the product by the width of the tract divided by 6; the resulting product will be the convergency required. (See Fig. 34.)

To obtain the convergency of the meridional boundaries of any tract bounded by section lines, or other lines of legal subdivision, within a township, proceed as follows: Divide the tract into the least possible number of rectangular parts and compute the convergency for each tract; then, take the sum of the convergencies thus determined. (See example, Fig. 36). The convergency of two meridians of equal length, in the same latitude, is proportional to their distance apart; e. g., the convergency of two meridians 6 miles long, separated by 5 ranges, latitude 38° , is $56.8 \text{ lks.} \times 5 = 2.84$ chains.

Convergency of meridians in the same latitudes, and not exceeding 24 miles in length, may be computed by an approximate proportion, which combines the advantages of convenience with an accuracy sufficient for the ordinary wants of the land surveyor; the proportion is this: *The cosines of the latitudes are to each other as the lengths of the intercepted parallels.* The following example illustrates the use of this rule:

The distance between the Principal Meridian and first range line west, in latitude $42^\circ 39' 07''$, is 6 miles; what is the convergency of the two range lines at the Base Line, the meridional distance being 24 miles?

$\cos 42^\circ 39' 07'' : \cos 43^\circ :: 480.00 \text{ chs.} : 477.31 \text{ chs.}$, which proportion may be worked with natural cosines, or more expeditiously by logarithms, as follows:

a. c. log cos	$42^\circ 39' 07''$	0.133427
log cos	43°	9.864127
log	480.00	2.681241
log	477.30	<u>2.678795</u>

The difference..... 2.70 chs. is the convergency required.

ac = Convergency on the Parallel.

abc = Angle of Convergency.

Table 13; opposite Latitude 44° , will be found 70.1 links, the convergency.

North Boundary = $480.00 - 0.70 = 479.30 \text{ chs.}$

For Convergency of the meridians sh and fg , we have:

$70.1 \times \frac{1}{3} \times \frac{1}{3} = 17.15 \text{ Links}$, as in the text.

Fig. 34.

Required the Convergency for a Township in Lat. $38^\circ 29' \text{ N.}$

From Table 13:

Convergency in Latitude $38^\circ = 56.8 \text{ Links}$;
 $39^\circ = 58.8 \text{ "}$

Difference = 2.0 "

Fig. 35.

Also; $29' = 0^\circ.48$;

then, $0^\circ.48 \times 2.0 = 0.96 \text{ links}$;

$ac = 56.8 + 0.96 = 57.76 \text{ links}$, the convergency required.

North boundary = $478.86 - 0.58 = 478.28 \text{ chains}$.

* Taken to nearest whole link.

Tabular Convergency, is 80.6 links.

Convergency for the tract $abcdefgh$:

Conv. of A; $80.6 \times \frac{1}{3} \times \frac{1}{3} = 22.39 \text{ links}$;

" " B; $80.6 \times \frac{1}{3} \times \frac{1}{3} = 13.42 \text{ "}$

" " C; $80.6 \times \frac{1}{3} \times \frac{1}{3} = 8.96 \text{ "}$

Convergency Required = 44.77 "

Also;

Conv. for E. tract is 17.92 "

" S.W. " 17.91 "

Total convergency 80.60 links, for Township.

Fig. 36.

Stadia.—Transits may be ordered with stadia, usually without pence. The stadia is a ring or diaphragm inserted between the eye and the center of the telescope, and across which are stretched two wires, called "stadia wires," so spaced that they will subtend a on a leveling rod equal to 0.01* the distance of the rod from a point *P* (where the visual rays cross), a few inches (=the focal) in front of the objective. The distance from the center of the ent (intersection of plumb-line with telescope) to the point *P* for instrument is called the "constant" for that instrument.† This con- its coordinate values if the line of sight is not horizontal, must be the values reduced from stadia readings. Stadia Reduction Table, following, was calculated by Mr. Arthur for use in the Pennsylvania Geological Survey, and may be used g the horizontal distance and the elevation of an object located from sit by stadia.

EXAMPLE OF USE OF TABLE.

me "constant" for instrument = 1.00;
ia reading on rod = 4.26 ft. (rod always vertical);
instrument is set up over a hub whose elevation is known, and
to a point on rod whose reading, from the middle cross-wire, is
height of instrument above the hub; and in this position the stadia
and the vertical angle are taken.)
ical angle = $12^{\circ} - 19'$. Then from Table, by interpolation:
al dist. of object from inst. = $95.45 \times 4.26 + 0.98 = 407.60$ ft.
dist. of object from hub = $20.84 \times 4.26 + 0.22 = 89.00$ ft.

FORM OF FIELD NOTES. (Left-hand Page.)

(Right-hand page is for notes and sketches.)

Sta.	Hor. Ang. †	Vert. Ang.	Cor. Dist.	Diff. in Elev.	Elev.
me nt at Sta 84	318° - 30'	(Elev. = 287. 5). 12° - 19'	5). Zero (ho 407.6	r. ang.) on 89.0	83. 376.5

y ratio may be used when ordering; but 0.01 is usual and con-
The diaphragm may be ordered with the stadia wires either "fixed"
stable."

ch instrument has its particular "constant," whose value is fur-
y the maker, and may vary from 0.75 to 1.25 ft. The constant is
the distance from center of instrument, or axis, to the objective,
the instrument is focussed on a distant object, *plus* the focal distance *f*,
ce from the plane of the cross-wires to the objective. Hence, the
for any instrument may readily be found by focussing to some
object and measuring from the objective to the cross-wires and to
er of the axis, and adding these measurements together. This sum
e distance from center of axis to the point *P*, noted above.
asured right-hand from back-sight [Sta. 83] up to 360°.

16.—STADIA REDUCTION TABLE.
For Reduction of Stadia Readings to Horizontal Distances and Elevations.

Leveling Correction for Earth's Curvature and Refraction.—A level "surface" around the earth is a spheroid. Now this spheroid is of the exact size and shape of the "mean" earth when every point of its surface is at zero elevation, corresponding generally with mean sea level. This is the datum spheroidal "plane" used in leveling. Any "plane" above said datum, i. e., at a higher elevation, if extended around the globe, will form a spheroidal level surface whose *perpendicular distance* from the datum plane will be constant at points of equal latitude; but will decrease gradually from the equator toward the poles. Hence, a meridian line of levels if run at a considerable height above the datum plane would be subject to correction; but the errors are generally so small compared with other errors that it is disregarded in practical leveling.

Ordinary sources of error in leveling are eliminated by taking equal back-sights and fore-sights and by using other precautions. Those due to curvature of the earth and refraction of light rays passing through the atmosphere must be *corrected*, where a single sight is taken on a distant object from a fixed position of the level. Let t (Fig. 37) be the point of sight of the telescope and let it be required to find the elevation of the point p upon which rests a leveling rod hp . Let the point l on the rod be at the same elevation as t ; then lp , the desired height, is the height of instrument above p , and the radius of the curve tl is the radius of the earth. If no atmosphere were present to cause refraction, the line of sight would be the horizontal line th , but on account of refraction the real line of sight takes the curve tr whose radius is about 7 times the radius of the earth; hence $hl = 7$ times hr , or $rl = \frac{1}{7}hl$ (nearly). Now as tr and tl are short curves of very large radii we may consider them as parabolas and intersecting the leveling rod at angles of 90° . If D represents the horizontal distance from instrument to rod, we have, from the nature of the problem, that hr , rl and hl are each proportional to D^2 . Moreover, while the correction for curvature *adds* to the apparent elevation of the distant object, the correction for refraction *subtracts* from this by about $\frac{1}{7}$ part. The combined (difference) correction for curvature and refraction is *additive*, as per the following table.

Fig. 37.

59.—RAILROADS.

A.—GENERAL DISCUSSION.

Existing Mileage, etc.—There are (1907) about 212,500 miles of steam railroads in operation in the United States, or one mile to each 400 inhabitants. The total assets of these roads are estimated at \$15,500,000,000 or \$73,000 per mile or \$180 per inhabitant; the gross annual earnings, \$2,000,000,000 or \$9400 per mile or \$23 per inhabitant; and the annual operating expenses, \$1,340,000,000 or \$6300 per mile or \$16 per inhabitant. There are about $7\frac{1}{2}$ miles of line per 100 sq. miles of land, equivalent to 13.8 sq. miles per mile of line.

Both the earning capacity and operating expenses of a road are dependent to a greater or less extent upon its location: the former upon the general route selected, and the latter upon the detailed location adopted by the engineer. This last factor embraces the two important subjects of gradients and Curvature, and the problems which confront the locating engineer are: What shall be their maximum values on a particular line on a particular Division? and what price shall be paid for their *reduction*, per cent of grade and per degree of curvature? These questions, especially the former, also appear constantly during the *operation* of the road, in the ordinary *improvements* of the line.

Economic Principles.—Private capital very seldom seeks investment unless it "promises" to be a paying one *from the start*, and railroad building offers no exception to this rule. In the design and construction of works of public utility from public funds, provision is made for future increase of population, on the grounds of economy. For instance, the estimated population 10 years hence is generally assumed as a basis for determining the capacities of reservoirs and sizes of distributing mains for domestic water supply systems installed in cities and towns. The reason for this is that they are works of quite permanent character and cannot be "enlarged" without great expense. Hence we have an illustration of a plant over-efficient for a number of years after construction, but economically so because the cost of gradually increasing the capacity of the plant would have exceeded the interest on the surplus capital invested in the beginning. On the other hand, let us take the case of a growing industry such as a manufacturing plant. Provision is here made (wisely) for future expansion of business. The site is selected where additional land may be purchased when required. Additional buildings are erected also when needed. There is but little surplus or idle capital invested in the plant dependent on the growth of the business, and furthermore, when additions are made, machinery of the latest pattern is installed. Thus the plant is efficient and economical at all times.

Railroad Projection cannot be governed wholly by either of the above extreme cases. The first would require too great an outlay at the start which would not be warranted by the early receipts of the road, and the second would make subsequent improvement too expensive. The New York West Shore and Buffalo Railroad is an example of a brand new road made to order for future generations, while the Pennsylvania System is built up of short lines which served at one time local interests. The first named now caters to second-class traffic, while the second has grown strong by virtue of its natural location and expansion. On the other hand there are roads which have been too much localized. They can never become "through" lines unless they reduce their *gradients* and *curvature*, and the "through freight" traffic is usually the best source of revenue. Exceptions may be made, however, to some small roads like the Columbia Southern and the Central of New Jersey, where the prevailing freight traffic (coal, in the latter case) is in one direction—that of the descending grades.

Gradients, in a line, may be established either (1) from necessity, as when the two terminal points to be joined together are at different eleva-

tions above sea level; (2) to reduce distance, as in passing over a long range of hills instead of around it; (3) to reduce the cost of construction incident to deep cuttings, high embankments and long tunnels.

The "ruling" grade on a location is the maximum grade allowable on any part of the line, and is sometimes called the "limiting" grade. For mountainous sections it is generally fixed at about 2%, more or less, and arbitrarily adhered to* by the locating engineers. Sometimes, however, the ruling grade is changed after location is begun. If a low mountain pass is discovered it may be decreased; if certain unforeseen difficulties are encountered in the topography of the country it may be increased. It is always best to have the heavy grades bunched together continuously if possible and not scattered throughout the line. By this arrangement they may be taken from the class of "limiting" grade, for single engine trains, and placed in the class of "pusher" grade, where assistant engines or pushers can be operated economically at one point. In this way the limiting grade proper, on the line, may be said to be lowered, which is decidedly advantageous to the reduced operating expenses of the road.

The Traction Force of a locomotive is the train resistance which it can overcome. It cannot exceed the "adhesion" of the driving wheels to the rails; the "adhesion" should not exceed the "cylinder" power of the engine; the "cylinder" power should not exceed the "boiler" power. We will assume then, that the engine is properly designed: that the cylinder power is a little in excess of the adhesion, and that the boiler power is just sufficient to cause slipping of drivers, when using sand. Then *tractive force equals adhesion*. The adhesion or tractive force may be assumed, for our present purpose, at $\frac{1}{4}$ the total weight on the drivers, that is, this force can be exerted horizontally in moving the train.

The train resistance on a level track comprises rolling friction proper, journal friction, reduced effect of traction due to curvature, air resistance, etc. We will assume it to be about 8 lbs. $\frac{1}{4}$ per short ton or $\frac{1}{250}$ the total weight of train—engine, tender and cars. Hence, using the same unit of weight throughout,

$$\text{Traction force} = \frac{\text{Total wt. on drivers}}{4} - \frac{\text{Total wt. of train}}{250} - \text{Train resistance} \quad (1)$$

$$\text{Total wt. of train} = 62.5 \times \text{total wt. on engine drivers} \dots \dots \dots (2)$$

$$\text{Gross car loads} = 62.5 \times \text{total wt. on drivers} - \text{wt. of engine and tender} \dots (3)$$

$$\text{Net car loads} = 62.5 \times \text{total wt. on drivers} - \text{wt. of engine, tender and empty cars} \dots \dots \dots (4)$$

The effect of an ascending grade on train resistance is calculated easily. The level-grade tractive force is simply increased by the total weight of train $\times$ the rate (or %) of the grade $\frac{1}{100}$. Hence, for any ordinary grade and using the same unit of weight throughout, we have, from (1),

$$\text{Tractive force} = \frac{\text{Total wt. on drivers}}{4} - \text{Total wt. of train} \left(\frac{1}{250} + \text{rate of grade} \right) \dots \dots \dots (5)$$

$$\text{Total wt. of train} = \frac{\text{Total wt. on drivers}}{.016 + 4 \times \text{rate of grade}} \dots \dots \dots (6)$$

$$\text{Max. rate (or \%) of grade} = \frac{\text{Total wt. on drivers}}{4 \times \text{total wt. of train}} - .004 \dots \dots \dots (7)$$

* Compensation amounting to .04 (or .05) % of grade per degree of curve is introduced in order to equalize the tractive resistance.

† May vary from $\frac{1}{4}$ to $\frac{1}{2}$; recent experiments give 0.23 to 0.235.

‡ May vary from 4 to 10; 7 to 8 lbs. is usually assumed.

|| This is a slight approximation. The rate (or %) of grade is equal to

$\frac{v}{h}$ or tangent α (Fig. 1), the angle of inclination which grade line makes with the horizontal, whereas the multiplier should be $\frac{v}{l}$ or sine α . For such slight inclinations as railroad grades the error is inappreciable. It is on the side of safety.

Fig. 1.

blem 1.—An engine with tender weighs 138 tons. The weight on
vers is 80 tons.

nd total weight of train for a level haul?

nd total weight of train for haul up a 1% grade?

nd the ruling grade for a total train weight of 833½ tons?

solution.—For (a) use (2), (b) use (6), (c) use (7); then,

total weight of train = $62.5 \times 80 = 5000$ tons.

total weight of train = $\frac{80}{.016 + .04} = 1429$ tons.

iling (maximum) grade = $\frac{80}{3333} - .004 = .02$, or 2% grade.

e.—As the engine and tender weigh 138 tons this amount must be
ed from the total weight of train to get the gross-car-loads. To find
freight the weight of empty cars must also be deducted. The
of cattle-, box- and coal cars is about $\frac{1}{10}$ * their normal capacity;
- and platform cars, $\frac{1}{3}$. Hence if the above train of 833 tons is a
rain the net freight would = $\frac{2}{3}(833 - 138) = 496\frac{2}{3}$ tons, or about $\frac{2}{3}$
al weight of the train for a 2% grade. If we take into consideration
ght of the caboose and also that the cars are not all loaded to their
capacity, the ratio of net freight is still further reduced. Moreover,
o of weight on the drivers, approximately,—

l weight of engine and tender, is.....	1 : 1.725;
l weight of train.....	1 : 10.417;
ht of train minus engine and tender.....	1 : 8.692;
freight (cattle) only, not including wt. of cars.....	1 : 6.200.

following table is calculated from equation (6) and gives the total
of train (including engine and tender) which may be hauled up
grades, assuming the weight on the drivers as *unity*.

at is, weight empty = $\frac{2}{3}$ weight loaded.

1.—RATIO OF TOTAL WEIGHT OF TRAIN, *T*, TO WEIGHT ON DRIVERS, *D*, FOR VARIOUS GRADES.

(Weight on Drivers, *D*, Assumed as Unity.)

Calculated from Formula 6, preceding.

Rate of Grade.			Rate of Grade.			Rate of Grade.		
Per 100.	Ft. per Mile.	Total Wt. of Train. $\frac{T}{D}$	Per 100.	Ft. per Mile.	Total Wt. of Train. $\frac{T}{D}$	Per 100.	Ft. per Mile.	Total Wt. of Train. $\frac{T}{D}$

1.00	52.800	17.86	2.00	105.600	10.42	3.00	158.400	7.35

Note.—To find the gross weight of train behind the tender: Multiply the weight of the driving wheels by the figures under "Total wt. of Train," for the particular grade, and deduct weight of engine and tender.
For the net freight, multiply this result by $\frac{1}{2}$, approximately; but see page 993.

The Allowable Expense for Grade Reduction will now be considered. A few hints only can be given and these based on data of very general character. Let Fig. 2 represent a modern freight train, in which

Fig. 2.

D = weight on engine drivers (consolidation type);

L = weight of locomotive and tender = $1.725 D$;

T = weight of train (multiplying values $\frac{T}{D}$ in preceding Table by D);

C = weight of loaded cars, which (see Table 1) = $\left(\frac{T}{D} - 1.725\right) D$;

F = weight of net freight hauled, which = $\frac{1}{2} \left(\frac{T}{D} - 1.725\right) D$, approx.

We will assume that trains are made up and hauled over a Division of 100 miles, without regard to the nature of the traffic on the balance of the road; that there are 1,000,000 tons of freight annually, hauled by 138-ton engines with 80 tons on drivers; that the cost per train mile is \$1.00; and that no pusher engines are used.

Fig. 3.

Ques.—What will be the ruling grade* on the Division, provided a saving of \$200,000 can be effected in cost of construction for each 0.1% grade above a level grade; the interest value of money being at the rate of 5 per cent?

Ans.—We can calculate readily the cost of hauling this freight by determining, for various grades, from the preceding discussion: (1) The net freight $F = \frac{1}{2} \left(\frac{T}{D} - 1.725\right) D$, hauled per train; (2) The number of trains per year required to haul the 1,000,000 tons; (3) The total cost of haul, at \$1.00 per train mile. Column (4), in the following table, gives the increased cost of the annual haul for any grade over that for a grade 0.1 per cent less. Column (5) shows the annual interest on the \$200,000 at 5 per cent, which equates nearly with \$9910 in column (4), opposite a 2% grade, which is therefore the required ruling grade. Any other rate of interest than 5 per cent would equate differently and give a different ruling grade. Of course other considerations naturally affect the problem to a greater or less extent.

Remarks.—Problems of this character are, in their nature, extremely concrete, and therefore cannot be truly represented by merely abstract formulas, which serve only as guides. For instance, the probable increase in future traffic (either immediate or remote) should be taken into account. If the future traffic is almost certain to be immediately and largely increased, the grade reduction should be proportionately great. Another fact to be borne in mind is, that the cost of grade reduction after track is laid is much greater than before, and especially so when under heavy traffic. But, as a compensating effect, the road is better able to stand this extra expense at such a time, both as to available cash and traffic economy. The "Lake Shore" road has expended hundreds of thousands of dollars in reducing grades by a small fraction of one per cent for a distance of a few miles, and while this work was going on the writer counted on one Sunday, 27 sections of a "single freight train."

* Of course the grade must be assumed to be long so the momentum of the train cannot be counted on as affecting the problem.

2.—COST OF HAUL ON VARIOUS GRADES.

And determination of Ruling Grade.

(See preceding discussion.)

Grade per 100.	Net Freight per Train. Tons.	No. of Trains per Year Required.	Total Cost of Hauling 1,000,000 Tons at \$1 per Train Mile	Increased Cost of Haul over that for grade 0.1 lower.	Interest on \$200,000 at 5%.	Remarks.
	(1)	(2)	(3)	(4)	(5)	
Level	3472.9	287.9	\$28,790	0		Direct loss if grade is reduced below 2%; but justified, possibly, if based on future increased traffic, higher cost per train mile, or lower cost for grade reduction or interest.

2.9	334.4	2991.5	299,150	11,560		
3.0	321.4	3111.1	311,110	11,960		

Curvature, * with increased Distance, in a line may arise from four primary considerations, namely, (1) to increase the revenue of the road by passing through towns not on an air line between terminal points; (2) to reduce cost of construction, as by avoiding deep cuts, high fills, long tunnels, expensive bridge crossings, etc.; (3) to reduce cost of operation, as by avoiding steep grades; and (4) to reduce cost of maintenance, as by choosing a line with a permanent roadbed, cheaply maintained, instead of a "structural" line involving much expense in repairs and renewals.

(1). In a new country, thinly settled and without competing roads, any departure from an economically located "air" line, to tap a lateral region, is justifiable when the "richness" of that region is about proportional to the additional cost of reaching it, assuming that the cost per mile of such changed line as well as its future growth of business will be, say, proportional to that of the whole line. If there is any question on this latter point it may better be tapped by a spur. The population of a region is in no wise the only safe criterion on which to base probable business. A cattle-raising country sparsely populated is very deceptive in this respect.

(2). We have just considered a case (1) where increased curvature (and distance) on a line would be justified by an increase in revenue about

proportional to the increased cost of the line. Let ABC , Fig. 4, be such a line giving increased revenue over the direct line AaC . We will consider now whether some change in location from AaC would be justified by reduced cost of construction,

Fig. 4.

of such amount that the annual interest on same would be equal to the increased net revenue received in case (1)? In the first case the line ABC is considered more expensive to construct than the line AaC , while in the present case the longer line is cheaper. As a matter of fact there is no relation between the two cases, although at first glance there appears to be. In the former case we are increasing our business say proportionately to our investment by running the line through B . In the latter case we are not willing to increase the length of our line to pass through B , but rather through some point B' (where there is no business) so that the annual increase in the operating expenses on the line $AB'C$ over that of AaC shall not exceed the interest on the decreased cost of construction. The actual cost of the line between A and C is another matter. This should be fixed within certain limits, however, having due regard to the amount and quality of traffic between $O-O'$, the terminal centers-of-gravity of haul; and also to the quality of the improvements made on those parts of the line AO and CO' . If the bulk of traffic is "through" traffic, O and O' may be considered practically to be at the terminal points of the line.

(3). Let us now suppose that instead of a deep cut or tunnel on the line AaC (Fig. 4) as in the preceding case (2), we are confronted with a long ridge which will have to be surmounted with heavy grades if the "air" line is to be maintained. Here we may resort to the expedient of selecting some route as AbC , carrying with it reduced grades and increased curvature and distance. In fixing the new route we now apply the opposite rule to that of case (2): The line should pass through some point b so that the annual decrease in the operating expenses on the line AbC over that of AaC should exceed the interest on the increased cost of construction.

(4). The cost of maintenance should generally be considered as a part of the "operating" expenses in the two preceding cases, (2) and (3). But the term may have a greater significance apart from such association. Two lines having equally objectionable grades may be constructed, (a) following the natural contour of the country, and (b) shortening the distance and cutting out curvature by the use of bridges and trestles. The difference in cost of maintenance and renewals in favor of (a) may outweigh all other considerations against it. The increased curvature would have to be considerable to become a serious matter, as the cost of maintaining curved track is but slightly more than that for maintaining straight track. The fee of ties in curved track is shortened from 3 to 5% annually per degree of curvature. The excess cost per train mile is inappreciable for a slightly increased length of line (not at all proportional to the length), and it is so but slightly affected by the introduction of moderately flat curves. Steep grades are especially to be avoided.

* Curvature is used, generally, in this discussion, in its broadest sense as including distance.

Location of the Line.—This comprises three main operations, as follows:

- B. Reconnaissance, or general field inspection.
- C. Preliminary Survey, with instruments.
- D. Location, or final determination of the line.

Topographical maps of many sections of the country may be had from the Government and from the several States. Those of the geological surveys are especially valuable in fixing the general route of the line in the reconnaissance and in the subsequent detailed surveys.

B.—THE RECONNOISSANCE.

This is the Field Examination necessary in fixing the "critical" points on the line, prior to the preliminary survey, in order to reduce the expense of the latter. It picks out the low mountain passes, the tunnel locations, and the favorable river- and other crossings. If well conducted it may dictate also, within close limits, the ruling grade and maximum curvature. The principal instruments used are the aneroid barometer, thermometer, pedometer (if on foot), cyclometer (if by wheel), odometer (if by wagon). These three latter are used for measuring the distance traveled. A hand level will be found useful, also a pocket compass, if detailed information is necessary in any particular locality. The thermometer is used in connection with the aneroid barometer. The transit with stadia is often used advantageously at this early stage. (See Stadia Reduction Table, page 984.)

The Aneroid Barometer is useful in determining the altitude of any point above sea level, or the relative difference in altitude between two or more points. It consists of a small, circular, air-tight box, in vacuo, with one side sensitive to the pressure of the atmosphere outside. The heavier the atmospheric pressure (the lower the altitude) the more it is pressed inward, and this movement is multiplied and transmitted to a recording index, like the hand of a clock, which denotes the pressure in inches (on the inner circle) corresponding to the mercurial column of an ordinary barometer. It is to be noted that outside the mercurial scale there is also a direct reading scale, to hundreds of feet, giving the direct altitude *approximately*. All aneroids now sold by the best makers are "compensated" for change or difference in temperature (see Fig. 5); but this does not mean necessarily that they are absolutely exact, but merely that they are nearly so and may be used "singly" with some degree of accuracy. When, however, extreme accuracy is required in getting the difference in elevation between two stations—one called the upper station and the other the lower station—two compensated aneroids are used, one at each station. Readings are taken at the same time and—

Fig. 5.

The difference in elevation = $(H - h) \left(\frac{900 + T + t}{1000} \right)$ (1)

in which H = reading in feet on elevation scale at upper station;

h = reading in feet on elevation scale at lower station;

T = temperature in degrees Fahrenheit at upper station;

t = temperature in degrees Fahrenheit at lower station.

If the temperature at both stations is 50°F. it is seen that $H - h$ represents the true difference in elevation, and there is no correction for temperature. Of course the aneroids will have to be compared by taking observations together at some station and the difference or index error noted for subsequent observations. The author has seen it stated by some of our prominent writers that the smaller aneroids of 1½ to 2½ inches diameter give as accurate results as the larger ones. The author's observations are to the contrary and are confirmed by the following from Messrs. Keuffel & Esser, New York City: "All our aneroids are compensated and their readings do not require any further corrections than the one referred to [formula (1)]

preceding]. It is our judgment that the small pocket aneroids are less accurate than the larger ones; not only are the dials of the larger instruments more closely graduated and permit of finer reading, but the larger instruments are also more sensitive on account of the larger size of their vacuum boxes. Furthermore, the instrumental error arising from the elastic reaction of the counter spring and rocker is greatly reduced."

The Mercurial Barometer is seldom used in railroad reconnaissance, having been supplanted by the aneroid, previously described. The aneroid is much more convenient to carry; there is no correction for latitude nor for variation in gravity due to altitude above the earth. For extremely accurate work, however, in establishing absolute elevations above sea level, the mercurial barometer is used. The following Tables are from Appendix 10, Report U. S. Coast and Geodetic Survey for 1881.

3.—BAROMETRIC ELEVATIONS FOR TEMPERATURE 50° F.

(For use with Mercurial Barometer.)

Note.—For temperatures other than 50°, see Correction Table, No. 4.

[Elevation in Feet above sea level.]

Ex. 1.—The mean temp. of two stations whose diff. of elev. is desired is 50° F. The barom. reading at upper station is 24.62 ins.; and at lower station, 28.165. Find the difference in elevation of the two stations.

Solution.—Using proportional differences—

Elev. upper station (24.62 ins.) = 5385 ft.

Elev. lower station (28.165 ins.) = 1720 ft.

Ans.—Diff. in elevation.... = 3665 ft.

4.—BAROMETRIC CORRECTION TABLE FOR TEMPERATURE.

(To be used in connection with Table 3, preceding.)

Note.—Mult. value obtained from Table 3, by the Coefficients in this table.

[Coefficients.]

Mean Temp.	Coef.	Diff. per Deg.	Mean Temp.	Coef.	Diff. per Deg.	Mean Temp.	Coef.	Diff. per Deg.
0°	.8975		30°	.9620		60°	1.0262	
10°	.9194	.00219	40°	.9834	.00214	70°	1.0472	.00210
20°	.9408	.00214	50°	1.0049	.00215	80°	1.0677	.00205
30°	.9620	.00212	60°	1.0262	.00213	90°	1.0879	.00202

Ex. 2.—Now for any other mean temp. of the two stations than 50° F., say 65° F., we find the coef. for mean temp. in Table 4, and mult. this into the result obtained from Table 3 for 50° F. Thus, for 65° F., the coef. is $1.0262 + .00210 \times 5 = 1.0367$. Solving Ex. 1, for a mean temp. of 65° F., we have $3665 \times 1.0367 = 3800$ ft. = diff. in elev. of the two stations.

C.—THE PRELIMINARY SURVEY.

The Organization for the preliminary survey, as ordinarily conducted, comprises full parties for transit, level-, and topographic work. This survey consists in developing a broken line on the ground, that can be used later as a base in projecting the final location. The preliminary line should be nearly identical, practically, with the final location so that the latter will be "fully covered" by the topography. In cases where it is evident that any part of the location will be radically different from the preliminary line as run, a new preliminary line should be run immediately covering that portion, and the old line "abandoned" and marked so in the note books. Equated stationing should be used instead of introducing the terms "long station" or "short station."

The Locating Engineer will select, usually, some critical point where the line has to come, in both position and elevation, for a starting point of the survey. Where a mountain range has to be crossed it is customary to begin at the summit and work down, but this does not always hold. If there is no pass low enough, and a tunnel is imperative, it is often necessary to make a quick topographical survey "along" the main range, running transverse lines from the main summit line at points where it is thought the length of tunnel will be the least, at the desired elevation. This will not necessarily be at the "pass" and may be a considerable distance from it. (In connection with tunnel location, the geological formation should be studied and also the possibility of one or more shafts to facilitate construction.)

The Transitman should be careful to hold closely to any grade line which may have been decided upon from the reconnaissance data. For this purpose the transit should be provided with a Gradienter Screw by which the telescope may be inclined to the required grade. It consists of a clamp and slow-motion screw, so that one complete revolution of the latter raises or lowers the line of sight of the telescope 1 foot vertically in a horizontal distance of 100 feet. The edge of the head is divided into 100 parts for minute readings, and the number of complete turns of the screw are indicated by a graduated bar. Stakes are set every 100-ft., or station, and hubs at every transit point. In a true preliminary line no curves are run, but it is sometimes convenient to fit in a curve around a hillside to facilitate the work of topography and later location. The accuracy with which preliminary lines are run depends somewhat upon the circumstances of the case. The policy of the Southern Pacific R. R. Co. is to run very accurate preliminary surveys so that the subsequent location can be calculated to a nicety in the office. Magnetic bearings should be taken at every position of the transit, as a check on the angles.

Ex. 1.—The grade of a road is 95.3 ft. per mile; hence, grade angle = $1^{\circ} 01' 51'' + 12^{\circ}$.

The Levelman starts usually from an established bench mark (*B. M.*), frequently at an assumed elevation, as near as possible to the correct elevation above sea level. He follows closely behind the transitman, taking elevations on the ground at every station and also at intermediate points where the profile demands. He should keep the transit at the correct elevation at every transit point and sometimes give levels ahead of the transit. He establishes temporary bench marks on every transit hub, and permanent bench marks, say, every half mile. They should be described accurately in the note book by exact stationing on the line and by distance to right or left of same. Check levels should be run every 10 miles, more or less. If work is slack, the levelman can often aid the topographer over certain stretches by taking side levels. Two rodmen can often be used to great advantage. The combined target- and self-reading rod is the best—the former for turning points, and the latter for ordinary ground elevations.

The Topographer gets the ground elevations at stations on the center line from the levelman, either the night before or during the day, at intervals. His duties are to take such notes that contour lines can be platted accurately on the maps. It is perhaps needless to say that in some cases topography should be taken extremely accurate, and especially so if the location lines are determined primarily in the office. Perhaps the most common method of taking topography is with the hand level, for elevation, and by pacing, for distance. Often the (cloth) tape is used. There are two methods of keeping the notes: (1) To give the relative elevation at right angle to the center line at each station, and the distance out, to each break in the

ground, as $\frac{+4.3}{20}$; and (2) to "sketch in" the contour lines directly in the

field, giving the distances out from center line. The clinometer is very useful in moderately sloping country. The transitman may often help the topographer on very steep hillsides by taking vertical slope angles at right angle to the line.

The Mapping consists in platting the instrument line from the transit notes, and the topography or contour lines from the topography notes. The former may be platted with a protractor or by tangent- or chord deflection,* from each previous tangent line; or a base (say north and south) may be established on the map from which each tangent line is laid off by calculated angle. Sometimes the lines are platted from calculated latitudes and departures of the angle points or points of intersection (*P. I.'s*) of the tangents. This latter method has the advantage of accuracy. The magnetic bearings are a check on the calculated bearings of each tangent and errors of reading angles in the field, both in amount and direction.

D.—THE LOCATION SURVEY

The Location is the Objective, or the desired end sought; the other surveys are simply means to this end. The reconnaissance may sometimes be reduced to a mere inspection of the country in a most casual manner. The preliminary survey may often consist in running a few compass lines to determine the general route, or even these may be omitted. But the location survey consists in the final establishment on the ground of the line as it is to be built: running in the tangents and joining them with the proper curves. Of course there are generally minor changes in the line during its construction, but these subsequent changes might be considered part of the location proper.

The Profile and Grades are subjects for constant study; the latter even after the road is constructed and in operation. The grade line (= base of cut or top of fill, and is called sub-grade during construction) is usually adjusted to the profile by the use of a fine thread stretched over the latter in various positions, studying at the same time the "equalization of cuts and fills." By this phrase we do not mean necessarily that the quantities in the cuts should equal those in the fills, although this might hold true for certain saw-toothed profiles or profiles with short haul from cut to fill; and especially where the material in the cuts, instead of borrowed material, would naturally be used in the fills. If the material in cuts is rock, and borrowed material may be had more cheaply for the fills, the grade line would naturally be raised to reduce the cost of cutting. Generally, it may be stated that the grade line is so adjusted that the quantities in cut are

* See Table of Chords, page 959.

less than those in fill. In this connection see *earthwork tables*,* 0, etc.; and also notes on *shrinkage*, page 909.

Road Curves.—Curves are introduced in both the grade and aline-roads to give easy change of direction to moving trains. The *kind* used for either purpose is chosen by reason of its convenience in cut on the ground. Hence we use, generally, parabolic vertical or connecting grade lines, and circular horizontal curves for con-

angents. *Parabolic Curves* are easily calculated and laid out. The principle parabola is that the *offset* from a *fixed base* is proportional to the *distance in a uniform direction from a fixed point*. In Fig. 6,

Fig. 6.—Parabolic Vertical Curve.

the vertex or summit of two grade lines passing through A and B, respectively; and let it be required to put in a parabolic curve *AvB* of any say 800 feet. Then A and B, the limiting points of the curve, will be on either side of the vertex. Calculate the elevations of these two points. Produce AV to T and calculate the maximum offset TB. Then

the square of distance in *stations* from A to any other station is equal to the square of the vertical offset at that station from the line AVT to the parabolic curve.

$$\frac{TB}{8 \times 8} \times 4 \times 4 = \frac{TB}{4}$$
 The level and rod are used for vertical offsets, and the chain for horizontal distances. Valley curves are laid out in a similar manner to summit curves.

Horizontal Circular Curves may be simple, compound or reversed. To lay out a curve by the infinitely compounded curves—the parabola, and the circle; and also the many forms of spiral and easement curves are approximations to the latter.

Circular Curves are arcs of circles, and are denoted either by the radius or by the "degree of curve," generally the latter. The degree of curve may be defined as the angle subtended at the center of the circle by a 100-ft. station on the arc, whether the chord lengths are 100-ft. (used for flat curves as of 5° or less), 50-ft. (used for sharp curves from 5° to 10°), or 25-ft. (used for curves above 10° and for turnouts and switches). It is seen that the degree of curve is comparable with the radius only when the length of chord by which the curve is laid out, is given; hence,

100-ft. chords, the sine of $\frac{1}{2}$ the degree of curve	= 50 ft. ÷ radius in ft.
50-ft. " " " "	= 25 ft. ÷ " "
25-ft. " " " "	= 12½ ft. ÷ " "

Each the degree of curve may be obtained by multiplying the corresponding angles by 2, 4 and 8, respectively. Throughout the following tables 100-ft. chords will be assumed unless otherwise noted.

To lay out a simple curve of *D* degrees from a point, P. C. (called point of beginning of curve), situated on the tangent line *T*₁, Fig. 1, set up the transit at the P. C., and turn off, by addition, from the back-sight produced, the successive angles $\frac{D}{2}$ for each 100-ft. station. The

tables may be copied on profile paper in the form of cubic yards of cut and fill, station and arranged so that the quantities can be read off by matching the zero of the table to the grade line of the profile, and the quantity opposite the ground line. The tables are in feet, or to feet and half feet, and the heights are to the same vertical scale as the profile. *Caution:* Note that the quantities must be increased if the ground slope is not level.

angle $\frac{D}{2}$ is called the deflection angle per station and is always equal to $\frac{1}{2}$ the central angle per station; or $\frac{1}{2}$ the degree of curve, D . From this it will be seen that the *total* deflection angle to any point on the curve, from a tangent to the curve at instrument point, is equal to $\frac{1}{2}$ the *total* central

Fig. 7.—Circular Horizontal Curve.

angle subtended by the two points. Thus, the deflection angle to point 2 is $2 \times \frac{D}{2}$; to point 3, is $3 \times \frac{D}{2}$; and to the $P. T.$, is $(3+x) \times \frac{D}{2}$, in which x is any *decimal part* of a 100-ft. station. If, in Fig. 7, the degree of curve $D = 30^\circ - 30'$, and $x = 60$ ft., we have that the total deflection to the end of curve or point of tangent $P. T. = (3+x) \times \frac{D}{2} = 3.6 \times \frac{30^\circ - 30'}{2} = 6^\circ - 18'$; and that

the total central angle $= 12^\circ 36'$. Moreover, the central angle subtended by the *total length of curve*, from the $P. C.$ to the $P. T.$, is equal to the *angle of intersection* I at the point of intersection $P. I.$ of the adjoining tangents T_1 and T_2 produced. The portion of a tangent produced which lies between the $P. I.$ and the $P. C.$ or $P. T.$ is variously termed the "semi-tangent," "tangent distance" or "vertex distance." The length of a curve is the distance between the $P. C.$ and $P. T.$, measured in chord lengths, and not the true length of the arc. Thus, in Fig. 7, if the last chord x is $\frac{1}{2}$ of a 100-ft. station, the total length of curve is 360 feet. If the degree of curve is $3^\circ - 30'$, the radius $= 50 \div \sin \frac{3^\circ - 30'}{2} = 1637.28$ ft.; and if the angle of inter-

section I is $12^\circ - 36'$, the semi-tangent $= \text{radius} \times \tan \frac{12^\circ - 36'}{2} = 180.76$ ft.

The last is simply the solution of a right-angle triangle with hypotenuse joining O and $P. I.$, and with angle at the base (at O) equal to $\frac{I}{2}$. The "ex-

ternal" is the shortest distance from the $P. I.$ to the curve, and is measured along the hypotenuse just mentioned. Clearly, it is the length of the hypotenuse minus the radius, and in the present instance is equal to

$\text{radius} \times \text{exsec}^* \frac{12^\circ - 36'}{2} = 9.95$ ft. In fitting a curve in between two adjoin-

ing tangents of a preliminary survey, the external distance is often of primary importance in arbitrarily fixing the position (and degree) of the curve. When the degree of the curve is determined the semi-tangents are calculated and laid off from the $P. I.$, and the curve run in as explained above.

* Exsecant = secant - 1.

10.—RADII OF ENGLISH CURVES, IN FEET.* (Chords 100 Feet.)

Note.—See Foot-note for using this table for Metric curves.

* Semi-tangents and externals are (almost exactly) inversely proportional to the degree of curve D , for the same intersection angle I .† Table 11, above, may be used for Metric curves: Semi-tangents and externals in meters—values in above table mult. by $\frac{1}{100}$ chord in meters.c.—For chord = 20 meters, and intersection angle = 12° ; then semi-tang = $\frac{2.21}{5}$ meters, and external = $\frac{31.56}{5}$ meters, for a 1° curve.

12.—MINUTES AND SECONDS REDUCED TO DECIMALS OF A DEGREE OR HOUR.*

(Either Angular Measure or Time Measure.)

Note.—See Foot-note regarding use of this table.

*Ex. in Angular measure: 20° 35' 17" = 20° 35' 15" + 2" = 20.58804 deg.

Ex. in Time measure: 20h 35m 17s = 20h 35m 15s + 2s = 20.58804 deg.

The Various Problems in Simple Curves may all be solved without the use of formulas. It is necessary only to draw a sketch of the conditions of the problem for any particular case, set down the *known* data governing the case, and solve trigonometrically for the *unknown*. The position of the center of the circle or circular arc is the *key* to all solutions. A few hints will be given to illustrate:

To move a curve (shown in full lines, Fig. 8) joining two tangents (T_1 and T_2), so it will end (dotted lines) in a parallel tangent (T_3): The distance moved ($=m$) = the perpendicular distance between the tangents (d) + sine of intersection angle (I).

Fig. 8.

To change the radius r (full) to r' (dotted) so that curve ending in tangent T_2 shall end in parallel tangent T_3 (Fig. 9): The end of the new curve lies on the long chord as shown. Then $n = d + \sin \frac{I}{2}$, and

Fig. 9.

$r - r' = \frac{n}{2} + \sin \frac{I}{2}$; therefore $r' = r - \left(d + 2 \sin^2 \frac{I}{2} \right)$, in

which d = perpendicular distance between T_2 and T_3 . Or, $r' = r - d + (1 - \cos I)$ = $r - d + \sin^2 I$. The reverse holds true when radius is increased.

To join a curve (c) and a point (P) by a tangent (T_2): The tangent T_1 and the curve c fit the contour line around the hill H , and it is proposed to throw off a tangent T_2 , from some point on the curve, so it will pass through the point P , ahead. One practical method of doing this in the field is to assume the position of the $P.T.$, turn the angle for the tangent ahead, measure the distance and offset to P , and from this data calculate the true position of the $P.T.$, and "move ahead" or "back up" accordingly. If, however, the position of the point P has been located, the position of the $P.T.$ can be fixed accurately by calculation. Reduce the location of P (no matter how located) to the distance d from the center of the circle at o , and calculate the angle α . The distance r is the radius of the curve. This gives a calculated tie from the $P.C.$ to P . Now

Fig. 10.

$$x^2 + y^2 = r^2 \dots \dots \dots (1)$$

and $\tan \beta = \frac{x}{y} = \frac{y}{d-x}$; or $y^2 + x^2 = dx \dots \dots \dots (2)$

Equating (1) and (2). $dx = r^2$, or $x = \frac{r^2}{d} \dots \dots \dots (3)$

From which y , $\tan \beta \left(= \frac{x}{y} \right)$, $I \left(= \alpha - 90^\circ + \beta \right)$, etc., can be found.

Compound Curves are made up of two or more curves of different radii, directly joining each other, and curving in the same direction. They are not difficult of analysis. The key to the solution of any problem lies in putting the data in the right shape and working from the centers of the curves. Fig. 11

needs no explanation other than that the $P.C.C.$ is the point of compound curve, and the total angle of intersection between tangents T_1 and T_2 is the sum of the separate intersection angles I and i . Note also that the length of tangent to the $P.C.C.$ is equal to the $S-T$ of the large curve + the $s-t$ of the small curve; hence the total vertex distances, V and v , from the $P.C.$ and $P.T.$, respectively, bear a relation to the rest of the data.

The following table illustrates a few simple problems and solutions which may be had from Fig. 11. The known quantities are indicated by letters; and the answers required, by blank spaces in each line. The formula for solution in each case is at the right. Problems with other data may be reduced to these forms before solving.

Fig. 11.

13.—SOLUTIONS OF COMPOUND CURVE PROBLEMS.

(See Fig. 11).

Note.—Capital letters refer to the curve of larger radius; small letters to curve of smaller radius.

No.	Angles of Intersection.			Radii.		Vertex Distances.		Solution.
	$I+t$	I	t	R	r	V	v	
1		I	t	R	r			Solve for $S-T$, $s-t$, small triangle, V , v , ($I+t$).
2	$I+t$	I or t		R		V		$R-r = [R \text{ vers } (I+t) - V \sin (I+t)] + \text{vers } t$; and $v = R \sin (I+t) - (R-r) \sin t - V \cos (I+t)$.
3	$I+t$			R	r	V		$\text{Vers } t = [R \text{ vers } (I+t) - V \sin (I+t)] + (R-r)$; and $v = R \sin (I+t) - (R-r) \sin t - V \cos (I+t)$.
4	$I+t$			R		V	v	$\tan \frac{1}{2} I = [R \text{ vers } (I+t) - V \sin (I+t)] + [R \sin (I+t) - V \cos (I+t) - v]$; and $R-r = [R \sin (I+t) - V \cos (I+t) - v] + \sin t$.
5	$I+t$	I or t			r		v	$R-r = [v \sin (I+t) - r \text{ vers } (I+t)] + \text{vers } I$; and $V = (R-r) \sin I + r \sin (I+t) - v \cos (I+t)$.
6	$I+t$			R	r		v	$\text{Vers } I = [v \sin (I+t) - r \text{ vers } (I+t)] + (R-r)$; and $V = (R-r) \sin I + r \sin (I+t) - v \cos (I+t)$.
7	$I+t$				r	V	v	$\tan \frac{1}{2} I = [v \sin (I+t) - r \text{ vers } (I+t)] + [V + v \cos (I+t) - r \sin (I+t)]$; and $R-r = [V + v \cos (I+t) - r \sin (I+t)] + \sin I$.

Note.—For Nos. 1, 2 and 5, either I or t may be given.

Reversed Curves should be avoided, especially for main line traffic. This may be done by "separating" the two simple curves on either side of the point of reversed curve (P. R. C.) and joining them by a short

Fig. 12.

tangent. The curves may be separated by moving them back from the P. C. and P. T., or by making them "sharper." To find the relation existing between the known and unknown data in Fig. 12:

Let d = the length of the line joining the P. C. with the P. T.;

α = the angle which the line d makes with T_1 ;

β = the angle which the line d makes with T_2 .

Then $\sin A = \frac{1}{2} (\cos \alpha + \cos \beta)$, from which the angle A , is obtained:

$$I = \alpha + 90^\circ - A;$$

$$t = \beta + 90^\circ - A = I - \alpha + \beta;$$

and $R = (d \sin A) + (\sin I + \sin t) \dots \dots \dots (1)$

In Fig. 13 the distance d is measured between points on two tangents T_1 and T_2 ; and the angles I and t , which the line d makes with these tangents, are known. It is required to fit in a reverse curve of common radius R :

$$R = \frac{d}{\tan \frac{1}{2} I + \tan \frac{1}{2} t}.$$

Fig. 13.

The Cubic Parabola is the principal form of parabolic curve used, and is fundamental of most so-called spiral- or easement curves. The equation of the cubic parabola is $y = nx^3$, in which x is the abscissa, and y the ordinate to any point p , Fig. 14. The constant n is a decimal, and may have any value: small for a flat curve, and large for a sharp curve. If the cubic parabola is laid off by deflection angles from the point o on the tangent T , then the deflection angle* to point 1 is d ; to point 2, $4d$; to point 3, $9d$; to point 4, $16d$; to point 5, $25d$; etc. That is, while the ordinate y to any point p is proportional to x^3 , the deflection angle is proportionate to x^3 . It is to be noted also that x is measured along the tangent produced and not along the curve. The effect of this is, of course, to gradually increase the lengths of the "stations" from point o : as $4-5 > 3-4 > 2-3 > 1-2 > 0-1$. For this reason the cubic parabola has never been popular, but has given way to the spiral curve. Both of them are very flat at the ends and grow rapidly sharper toward the center of the curve.

Fig. 14.

The Spiral Curve is a modification of the cubic parabola. It is based on *chords of equal length*, with the curve compounded at the end of each chord. The chords may be of any length from 10 ft. to 50 ft., while 30 ft. is quite usual. The degree of curve of the first arc, subtended by the chord 0-1, is the common difference for the degree of curve of successive arcs. Thus, if the central angle of the curve 0-1 is A , then 0-1 will incline at an angle of $\frac{1}{2}A$ with the tangent T ; 1-2, at an angle of $\frac{3}{2}A \times 4 = 2A$; 2-3, $\frac{5}{2}A \times 9 = 4\frac{1}{2}A$; 3-4, $\frac{7}{2}A \times 16 = 8A$; 4-5, $\frac{9}{2}A \times 25 = 12\frac{1}{2}A$; etc. This can be proved by making the central angles $A, 2A, 3A, 4A, 5A$, respectively. The offsets from tangent T to points 1, 2, 3, etc. are calculated successively, knowing the length of chords and their angles of inclination with T ; as are also the horizontal distances between the offset lines, as x_1, x_2 , etc. Then, the tangent of the deflection angle from o to any point on the curve is $\frac{y}{x}$ †.

Fig. 15.

Simple Easement Curves are sometimes approximated from simple curves, as follows: Run out the regular simple curve from the tangent T as shown dotted. Lay off the required curve *inside*, by measuring the offset distance d from the outer curve. Lay off the point $P. S.$ of the spiral starting from the tangent, and also the end of the spiral at the $P. C. C.$ where it joins the new curve, *equidistant* from the point c , which bisects the offset distance d at the $P. C.$ The offset distance may average from 2 to 4 ft.; and the distance from $P. S.$ to $P. C.$ may vary from 50 ft. to 100 ft. The writer can recommend these curves for fast-train service. Note that the inner curve may be "run in" directly with the instrument, the outer curve being omitted.

Fig. 16.

E.—RIGHT OF WAY.

Filing of Location.—After the final location is adopted it is filed with the secretary of State for the particular State through which the line is projected. The following is a typical description of location: Beginning at a lake on the shore of Huron Bay, near high-water mark and westerly about 325 feet from the westerly corner of the old stone fort in the town of Hamford, county of Huron, and State of Ohio; thence north $84^\circ 30'$ west, four thousand three hundred ten (4310) feet to a stake in the county and in front of Judge Pritchard's farm-house; thence by a curve to the

* Approximately; but almost exact for flat curves. To be strictly exact, the "natural tangent of the deflection angle" should be substituted for "deflection angle."

† The "Railroad Spiral," by W. H. Searles, contains tables for laying out any spiral in the field, with instrument at any point on the spiral.

right, with a radius of nineteen hundred ten (1910) feet, a distance of three hundred fifty (350) feet to a stake; thence by a tangent to said curve North 74° West, 12652 feet to a stake - - - etc.

Purchase and Condemnation.—The Real-Estate Agent of the road is provided with maps of the located line showing land lines, owners' names, and widths of right-of-way desired through the various parcels of land. The usual width is 100 feet, but this should be exceeded in the case of heavy cuts and fills. The following table, No. 14, will be useful for reference in this connection. Where land cannot be purchased at a reasonable figure it may be condemned and the condemnation price so fixed is called an "award."

Oftentimes the award may include a parcel of land of considerable size, not required strictly for right-of-way purposes. In such cases it is a great mistake for the R. R. Co. to dispose of any of this land without first considering whether it is liable to be needed for a passing siding, or for a spur track to some prospective manufacturing plant. The writer can instance many cases in which supposed surplus property has been disposed of at a low figure and repurchased for an amount four or five times as great.

14.—TABLE FOR FINDING WIDTH OF RIGHT-OF-WAY FOR CUTS AND FILLS.

Note.—Total width between slope stakes = width of base of roadway + sum of horizontal distances for slopes (from table).

[Horizontal Distance in Feet for One Slope.]

Height in Ft.	Side Slope.											
	$\frac{1}{2}$ to 1.	$\frac{2}{3}$ to 1.	$\frac{3}{4}$ to 1.	$\frac{4}{5}$ to 1.	1 to 1.	$1\frac{1}{2}$ to 1.	$1\frac{2}{3}$ to 1.	$1\frac{3}{4}$ to 1.	2 to 1.	$2\frac{1}{2}$ to 1.	$3\frac{1}{2}$ to 1.	4 to 1.

120	24.0	30	60	90	120	150	180	210	240	270	300	

Ex.—Width of base of roadway = 28 ft.; height, 48 ft. (ground slope about level;) side slopes, $1\frac{1}{2}$ to 1. Then width between slope stakes = $28 + 60 + 60 = 148$ ft. (Retaining walls are often used to narrow the required right-of-way.)

R.—CONSTRUCTION.

Earthwork Calculations.—The preliminary and location survey maps and profiles should give all the information necessary to estimate the cost of constructing the line. Borings should be made or test-pits dug occasionally in order to classify the material in excavation. Several methods are used in making preliminary estimates of earthwork, and the three following are worthy of note:

(1).—The cross-section at each station, and at intermediate points if necessary, may be plotted on cross-section paper from the profile and

Fig. 17.

topography notes, as shown in Fig. 17. The distances D , d , H , h (and p) are then scaled and used in the following formula for area of cross-section in "cut," and similarly in "fill:"

Area in sq. ft. = $\frac{1}{2} [p(D+d) + 10(H+h)]$(1)

where 10 ft. is $\frac{1}{2}$ the width of roadbed in excavation. For quantities in fill, 10 would be replaced by 7, if the roadbed is to be 14 ft. wide. The cubical contents in feet of the solid figure of which the above cross-section is considered as the "average area" is found by multiplying this area by $\frac{1}{2}$ the sum of the distances to the adjacent cross-sections on either side. The summation of the contents in cubic feet is reduced to cubic yards, as the cost price is in that denomination. (Use planimeter if preferred.)

(2).—If the topography has been taken with a clinometer and the ground line is straight, as in Fig. 18, instead of broken as shown in Fig. 17, there are three methods in use for determining areas:

(a).—Plat the ground line G by means of the profile height h and the angle of inclination α ; scale G and H . Then, for the etched portion or cut: Area = $\frac{1}{2} GH - C$; in which C is the area of triangle below roadbed base, to V . In the figure, the constant C is 100 sq. ft. It varies with the side slopes and width of roadbed. (Use planimeter if preferred.)

Fig. 18.

(b).—Prepare tables of areas for various heights h , and various ground slopes α ; and for the standard roadbed and side slopes. For loose rock in excavation the side slope may be say $\frac{1}{2} : 1$; in embankment, 1 : 1. Earth 1 : 1 for cut, and $1\frac{1}{2} : 1$ for fill. The calculation of the table may be based on the following formula:

Area required, cut or fill = $\frac{1}{2}(h+v)^2 \cos^2 \alpha [\cot(\beta + \alpha) + \cot(\beta - \alpha)] - C$(2)

In which Area required = area of the etched portion in Fig. 18,

h = center height of cut or fill,

v = vertex distance below roadbed,

α = angle of ground slope with the horizontal,

β = angle of side slopes with the horizontal,

C = area of triangle (ht. = v) below roadbed.

When $\beta = 45^\circ$ the formula is somewhat simplified. It is to be noted that $(h+v)$ may be assumed as unity for various ground and side slopes, and afterward expanded by squares, finally deducting the value of the constant area C . The ground slope must not intercept the roadbed.

(c).—Tables may be prepared giving *correction areas* for slopes, to be added to tables for "level sections" (see Case 3), instead of tables of actual areas as previously described. From Fig. 18 it will be seen that sloping ground always gives a *plus* correction, as the small triangle below the elevated side of the ground line G is greater than the one above the depressed side. The correction tables may be for areas of cross-section, or

for cubic yards or cubic feet per station of 100 ft., 50 ft., etc. See Table 22, page 1080; also Table 27, page 1039.

(3).—Tables of "level sections" may be used in preliminary estimates where the ground is fairly "level;" or in connection with the previously described correction tables, where the transverse ground line is sloping. These tables may be calculated from the following formula, modified from formula (2), page 1016, by making $\alpha=0$, and using the previous notation:

$$A = \text{Area required} = (h+v)^2 \cot \beta - C \dots \dots \dots (3)$$

Or, giving $C (=v^2 \cot \beta)$ its value in terms of v and β ,

$$A = (h^2 + 2hv) \cot \beta \dots \dots \dots (3)$$

When the side slopes are 1 : 1, $\beta = 45^\circ$, and

$$A = (h+v)^2 - C = h^2 + 2hv \dots \dots \dots (4)$$

When the side slopes are $1\frac{1}{2}$: 1;

$$A = \frac{1}{2}(h+v)^2 - C = \frac{1}{2}(h^2 + 2hv); \dots \dots \dots (5)$$

and similarly for any other side slope.

These tables may be copied on profile paper in the form of cubic yards per 100-ft. station, and arranged so that the quantities can be read off directly by matching the zero of the table to the grade line of the profile, and reading the quantity opposite the ground line. The profile tables are usually to feet in height; or to feet and half feet.

18—MULTIPLICATION TABLE UP TO 60×60 . FOR FINDING AREAS OF CROSS SECTIONS

Note.—The Table is divided into Parts I and II. The greater factor denotes which Part to use and will be found as a heading over the Table. The smaller factor denotes which Part to use and will be found as a heading over the Table. The greater factor denotes which Part to use and will be found as a heading over the Table. The smaller factor denotes which Part to use and will be found as a heading over the Table.

Part II. Greater Factor, 31 to 60.

19.—UNIT AND DECIMAL AREAS OF CROSS-SECTION REDUCED TO
CU. YDS. PER 100-FT. STATION.

(See Table 20, following, for general use.)

Note.—The values in the table are cu. yds. per 100-ft. station corresponding to the unit area in the first column when used in the proper decimal place or denomination as per headings of columns.

[Cu. Yds. per 100-Ft. Station.]

Heading Multipliers.	Mil.	H	T	Thous.	h	t	Units	Decimals		Heading Multipliers.

Ex.—The average sectional area of one station (100 ft.) of the Culebra cut was 40600 sq. ft. Find the cu. yds. in the station?

Solution.—From above Table—

$$4 (5) = 148 148$$

$$6 (3) = 2 222$$

$$\underline{150 370 \text{ cu. yds. Ans.}}$$

20.—CUBIC YARDS IN 100-FT. STATION, FOR—
(Column headings are Units of numbers in first column.)

[Cu. Yds., from formula $\frac{100A}{3 \times 9}$.]

Ex.—Average area of cross-section
of station is 321.4 sq. ft. Find yardage
for station?

321. = 1188.9
(P. P. col.) .4 = 1.5
Ans. 1190.4 cu. yds.

—GIVEN AREAS IN SQ. FT. OF CROSS-SECTION.
(Move decimal point to right or left for both Areas and Cu. Yds.)

[Cu, Yds., from formula $\frac{100A}{3 \times 9}$.]

—Average area of cross-
 is 2583.7 sq. ft. Find
 for station?

$$(P. P. Col.) \quad \begin{array}{r} 2583. = 9566.7 \\ .7 = 2.6 \end{array}$$

Ans. 9569.3 cu. yds.

Remarks on above Table 20.

Table 20 gives the number of cubic yards in 100-ft. station corresponding in sq. ft. of cross-section up to 2700 sq. ft., equivalent to 10000 cu. 100-ft. station for the area named. The main table advances by areas, the units being at tops of columns; the Prop. Parts columns are for interpolation for tenths of sq. ft. Thus, for an average area section of 2622 sq. ft. the yardage per station equals 9711.1 cu. yds. If area is increased by 0.4 sq. ft. the yardage would be increased by 1.5 giving 9712.6 cu. yds for an area of 2622.4 sq. ft. By manipulating the decimal point to the right or left simultaneously for both areas and cu. yds., the range of the table may be extended. Thus, for an area of 2622.4 sq. ft. we have 9712.6 cu. yds. For areas up to 270 sq. ft. it will be found convenient to move the decimal point one place to the left, considering the headings as tenths of sq. ft. Thus, for an area of 262.2 sq. ft. we have 971.1 cu. yds., obtained by moving the decimal point for the yardage to the left also. For areas above 270 and up to 2700 sq. ft., the decimal in the table should be preserved. For average area of cross-section is for less than a 100-ft. station, say 50 ft., the yardage would of course be proportional, i. e., $\frac{1}{2}$ for 50 ft., etc.

21.—METHOD OF CALCULATING EARTHWORK TABLES FOR LEVEL SECTIONS.

(From a page of the writer's calculation of Table 26, page 1037.)

1st.—Select foolscap paper, horizontally ruled

2nd.—Draw vertical lines, in pencil, to represent the decimal points of numbers in columns 1, 2, 3, 4, 5, etc.; thus insuring the figures being "in column" and saving considerable time in making decimal points.

3rd.—Let w = width of roadway, in ft. ($w = 16$ in the present case); s = the side slopes of excavation or embankment (thus, in the present case, using slopes of $1\frac{1}{2}$ to 1, $s = 1.5$); h = height of level cutting, in ft.; and Q = quantity in cu. yds. per 100-ft station for a level cut or fill ground line.

$$\text{Then } Q = (2sh + 2w) \frac{h}{2} \cdot \frac{100}{3 \times 9}; \text{ or, } = (2sh + 2w)h \cdot \frac{100}{6 \times 9}; \text{ or, } = (sh + w)h \cdot \frac{100}{3 \times 9}.$$

Sometimes one and sometimes another of the above equations will be found most convenient, depending upon s and h .

4th.—Calculate Q for $h = 0.1$ as for line c , column 1*:

$$Q = (2 \times 1.5 \times 0.1 + 2 \times 16) 0.1 \times \frac{100}{6 \times 9} = 5.981 \text{ cu. yds. Similarly,}$$

$$\text{for } h = 0.2, Q = (2 \times 1.5 \times 0.2 + 2 \times 16) 0.1 \times \frac{100}{3 \times 9} = 12.074 \text{ cu. yds.}$$

∴ Diff. for 0.1 ft. from $h = 0.1$ to $h = 0.2$ ft. = 6.093 cu. yds. (See opp. line 1.) This number, 6.093, forms a primary base for calculating all the Differences (see numbers in *italics*) in the following table; and these Differences increase by a constant increment which will next be explained.

5th.—Find the successive Differences, lines 1, 3, 5, 7, etc. (in *Italics*), by calculating the constant incremental increase i for the particular slope s (in the present case $s = 1.5$) and for the successive increase in height d (in the present case $d = 0.1$ ft.); and adding this increment successively, using the first Difference, 6.093, as a base. Now the value of i in cu. yds. for any

slope = $\frac{2s}{3 \times 9}$ cu. yds.; therefore for slope of $1\frac{1}{2}$ to 1, as in the present case.

$i = \frac{2}{3} = 0.111\bar{1}$. Hence we have for Differences in column 1: 6.093 + 0.111 $\bar{1}$ = 6.204 (line 3); 6.204 + 0.111 $\bar{1}$ = 6.315 (line 5); 6.315 + 0.111 $\bar{1}$ = 6.426 (line 7); etc. Now glancing down the column we notice a similarity of the three groups of numbers, the number (Difference) in each group being a unit larger than the corresponding one in the group above. Hence it is essential that these Differences be arranged in groups, each successive group of Differences being set down from the preceding group by mental calculation. Note in this connection also that the Differences in successive columns are increased by 3.000 from those in the same line in the preceding column. Thus, 6.093, 9.093, 12.093, etc., indefinitely. Now, as to the number of Differences in each group, before repetition occurs: In the present case this number is 9 because $i = \frac{1}{9}$; for a slope of 1 to 1, $i = \frac{1}{4}$, therefore if 27 Differences are arranged in each column they will increase by 2.000 in line horizontally, when the slope is 1 to 1. Hence, the number of Differences in each column should be arranged for the particular slope. For a slope of $1\frac{1}{2}$ to 1, as in the present case, any number of groups of 9 will be convenient.

6th.—By successive addition, the quantities for each successive height h may now be obtained. Thus, for $h = 0.3$ ft., $Q = 18.278$ cu. yds.; for $h = 1$ ft., $Q = 64.815$ cu. yds.; for $h = 9.7$ ft., $Q = 1097.538$ cu. yds., etc.

Remarks.—The value of S at foot of each column is the sum of the Differences (in *italics*) in that column. Only one column need be added (these values of S are simply for checking the regular additions in each column) as the successive sums will increase by, in the present case, $27 \times 3 = 81$. Note method of checking each column by lines a , b and c .

* See table on opposite page.

$\frac{3}{4} : 1$	U	$\frac{h + \frac{1}{2}w}{1\frac{1}{2} - \tan \alpha}$ $\frac{h + \frac{1}{2}w}{1\frac{1}{2} + \tan \alpha}$ $h \cot \alpha$	$\frac{1\frac{1}{2}h + \frac{1}{2}w \tan \alpha}{1\frac{1}{2} - \tan \alpha}$ $\frac{1\frac{1}{2}h - \frac{1}{2}w \tan \alpha}{1\frac{1}{2} + \tan \alpha}$ 0	$\frac{(h + \frac{1}{2}w)^2 \tan \alpha}{3\frac{1}{2} - 2\frac{1}{2} \tan \alpha}$ $\frac{(h + \frac{1}{2}w)^2 \tan \alpha}{3\frac{1}{2} + 2\frac{1}{2} \tan \alpha}$ $\frac{h}{2} [h (\frac{1}{2} - \cot \alpha) + w]$	$\frac{100A}{3 \times 9}$ " $\frac{100A}{3 \times 9}$ " $\frac{100A}{3 \times 9}$ "
$1 : 1$	U	$\frac{h + \frac{1}{2}w}{1 - \tan \alpha}$ $\frac{h + \frac{1}{2}w}{1 + \tan \alpha}$ $h \cot \alpha$	$\frac{h + \frac{1}{2}w \tan \alpha}{1 - \tan \alpha}$ $\frac{h - \frac{1}{2}w \tan \alpha}{1 + \tan \alpha}$ 0	$\frac{(h + \frac{1}{2}w)^2 \tan \alpha}{2 - 2 \tan \alpha}$ $\frac{(h + \frac{1}{2}w)^2 \tan \alpha}{2 + 2 \tan \alpha}$ $\frac{h}{2} [h (1 - \cot \alpha) + w]$	$\frac{100A}{3 \times 9}$ " $\frac{100A}{3 \times 9}$ " $\frac{100A}{3 \times 9}$ "
$1\frac{1}{4} : 1$	U	$\frac{h + 0.4w}{0.8 - \tan \alpha}$ $\frac{h + 0.4w}{0.8 + \tan \alpha}$ $h \cot \alpha$	$\frac{0.8h + 0.4w \tan \alpha}{0.8 - \tan \alpha}$ $\frac{0.8h - 0.4w \tan \alpha}{0.8 + \tan \alpha}$ 0	$\frac{(h + 0.4w)^2 \tan \alpha}{1.28 - 1.6 \tan \alpha}$ $\frac{(h + 0.4w)^2 \tan \alpha}{1.28 + 1.6 \tan \alpha}$ $\frac{h}{2} [h (1 - \cot \alpha) + w]$	$\frac{100A}{3 \times 9}$ " $\frac{100A}{3 \times 9}$ " $\frac{100A}{3 \times 9}$ "

* Note that $\tan \beta =$ the reciprocal of $\cot \beta$; and that $\cot \beta =$ the ordinary ratio of "excav. or emb. slope" expressed as a fraction or decimal. Thus, for slope of $1\frac{1}{2} : 1 = 1\frac{1}{2} : 1 = 1\frac{1}{2} + 1$, $\cot \beta = 1\frac{1}{2} = 1.5$, and $\tan \beta =$ its reciprocal $= \frac{1}{1.5} = 0.66\bar{6}$, etc.

22.—FORMULAS FOR GROUND-SLOPE QUANTITIES.—Concluded.

To be added to, or subtracted from, quantities for level sections.
(For application, see Tables 27 and 28.)

Note.— x = hor. dist. (ft.) from cen. line to point where ground slope meets limit of section.
 y = vert. dist. (ft.) " " sub-grade

Note that Base, Slope, and Cu. Yds. in this table may all be multiplied by the same factor; thus, using factor of $\frac{1}{4}$ for height of 49.7 ft., we have, 24450 cu. yds. for base of 21 ft. and slopes $2\frac{1}{4}$ to 1.

Add for Tenths of Feet in Height.

P. P.

1.48

2.22

2.96

3.70

4.44

5.19

5.93

6.67

Use with preceding column only.

LEVEL SECTIONS (Earthwork); HEIGHT, 60-120 Ft.

USE OF ROADWAY, 14 Ft. SIDE SLOPES, $1\frac{1}{2}$ TO 1.

Use last two columns enable us to use any other base than 14 ft.: in height, 94.5 ft.: roadway 15 ft. Then we have, $54513 + 70 = 54583$ cu. yds. (See also Table 41.)

[Cu. Yds. per 100-Ft. Station.]

Add for Tenths of Feet in Height.

P. P.
7.41

Use with preceding column only.

25.—LEVEL SECTIONS (Earthwork); HEIGHT, 0-60 Ft.

BASE OF ROADWAY, 16 Ft. SIDE SLOPES, 1 to 1.

Note.—The last two columns enable us to use any other base than 14 ft.:

Ex.—Given height, 20.3 ft.; roadway 14 ft. Then we have, $2729.2 - (148.15 + 2.22) = 2578.8$ cu. yds. (For Ht. > 60 ft., see Tables 28, 40.)

[Cu. Yds. per 100-Ft. Station.]

	Ht. Ft.	.0	.1	.2	.3	.4	.5	.6	.7	.8	.9	Width of 2 Ft. Cu. Yds	
Note that Base, Slope, and Cu. Yds. in this table may all be multiplied by the same factor; thus, using factor of $\frac{3}{4}$ for height of 27.2 ft., we have, 3264 cu. yds. for base of 12 ft. and slopes $\frac{3}{4}$ to 1.	0		6.0	12.0	18.1	24.3	30.6	36.9	43.3	49.8	56.3		Add for Tenths of Feet in Height. 6.67

Use with preceding column only.

Note that Base, Slope, and Cu. Yds. in this table may all be multiplied by the same factor; thus, using factor of $1\frac{1}{2}$ for height of 47.3 ft., we have, 17160 cu. yds. for base of 27 ft. and slopes $1\frac{1}{2}$ to 1.

-CORRECTIONS FOR GROUND SLOPES NOT LEVEL.

BASE OF ROADWAY, 18 FT. SIDE SLOPES, 1 TO 1.

(See Explanation and Formulas in Table 22.)

Note.— α =angle of ground slope (G. S.) to right of left of center line; "G. S.=1:10," "G. S.=2:10," etc., means $\tan \alpha$. Up or (+) slopes from center indicate additive corrections, and down or (-) slopes subtract from quantities in table on opposite page for level sections.

itive (+) and subtractive (-) Corrections in Cu. Yds. per 100-Ft. Sta.]

Center Ht. Ft.	G. S.=1:10. $\alpha=9^{\circ}.7$		G. S.=2:10. $\alpha=11^{\circ}.3$		G. S.=3:10. $\alpha=16^{\circ}.7$		G. S.=4:10. $\alpha=21^{\circ}.8$		G. S.=5:10. $\alpha=26^{\circ}.6$

BASE OF ROADWAY, 18 Ft. SIDE SLOPES, 1 TO 1.**

Note.—The last two columns enable us to use any other base than 18 ft.:

Ex.—Given height, 88.5 ft.; roadway 17 ft. Then we have, $34908 - \frac{1}{2}(651.85 + 3.70) = 34580$ cu. yds. (See also Table 40.)

[Cu. Yds. per 100-Ft. Station.]

3.70
4.44
5.19
5.93
6.67

Use with preceding
column only.

Note that Base, Slope, and Cu. yds. in above table may all be multiplied by the same factor: thus, using factor of $\frac{3}{4}$ for height of 66.3 ft., we have 13800 cu. yds. for base of 12 ft. and slopes $\frac{3}{4}$ to 1.

Examples of Use of Table 28.

Ex. 1.—Find the number of cu. yds. in a 100-ft. station: roadway 18 ft., excav. slopes 1 to 1, ground slope 3 in 10 straight across, and center height 63 ft?

Solution:
Level cutting.....18900 cu.yds.
Up slope, add.... 4114
23014
Down slope, sub.. 2215

Ans......20799

Ex. 2.—Same, but slope "up" 4 in 10 to left of center, and "down" 1 in 10 to right?

Solution:
+ 18900 cu.yds.
+ 6400
- 873

Ans......+ 24427

—CORRECTIONS FOR GROUND SLOPES NOT LEVEL.

BASE OF ROADWAY, 18 FT. SIDE SLOPES, 1 TO 1.

(See Explanation and Formulas in Table 22.)

α = angle of ground slope (G. S.) to right or left of center line; S. = 1:10, "G. S. = 2:10," etc., means $\tan \alpha$. Up or (+) slopes center indicate additive corrections, and down or (-) slopes subtractive from quantities in table on opposite page for level sections.

e (+) and subtractive (-) Corrections in Cu. Yds. per 100-Ft. Sta.]

G. S. = 1:10. $\alpha = 5^{\circ}.7$		G. S. = 2:10. $\alpha = 11^{\circ}.3$		G. S. = 3:10. $\alpha = 16^{\circ}.7$		G. S. = 4:10. $\alpha = 21^{\circ}.8$		G. S. = 5:10. $\alpha = 26^{\circ}.6$

-G. S. = +2 in 10 to left of center, and -3 in 10 to right; center 30 ft. Then add 3667 cu. yds. to, and subtract 3385 cu. yds. from, i. yds. obtained from table of level sections on opposite page.

Interpolations for Table 28.

-When center height is in feet and tenths, interpolate for tenths from table.

-When the ground slope is intermediate between those slopes to head the columns, direct interpolation will be close enough for purposes for preliminary estimates, etc. Otherwise, use the exact in Table 22.

-When the roadway, w , is greater or less than 18 ft., multiply table by $\left(\frac{k + \frac{1}{2}w}{k + 9}\right)^2$.

29.—FORMULAS FOR EXTENDING TABLES OF LEVEL SECTIONS TO ANY SIDE SLOPES.

Side Slopes	For Use with Tables with Slopes $1\frac{1}{2}$ to 1.		For Use with Tables with Slopes 1 to 1.

	66	34	3															

Note.—R=width of bottom of canal or railway cut, or top of embankment. R may be increased or decreased by consulting the last two columns of the tables referred to.

Ex.—To find the number of cu. yds. in a 100-ft. station for a canal 120 ft. wide at bottom and with side slopes $1\frac{1}{2}$ to 1: Consult Table 21 and multiply the cu. yds. corresponding to any given height by the factor 6.

30.—LEVEL SECTIONS (Earthwork); HEIGHT, 0-60 Ft.

BASE OF ROADWAY, 18 Ft. SIDE SLOPES, 1½ TO 1.

Note.—The last two columns enable us to use any other base than 18 ft.:
 Ex.—Given height, 46.4 ft.; roadway 20 ft. Then we have, 15054 +
 0.74 + 2.96 = 15398 cu. yds. (For Ht. > 60 ft., see Tables 28, 40.)

[Cu. Yds. per 100-Ft. Station.]

Note that Base, Slope, and Cu. Yds. in this table may all be multiplied by the same factor; thus, using factor of 0.8 for height of 28 ft., we have, 2240 cu. yds. for base of 16 ft. and slopes $\frac{1}{4}$ to 1. (Slope $\frac{1}{4}$ to 1 is frequently used in solid rock excavation.)

Add for Tenths of Feet in Height.

P. P.
7.41

Use with preceding column only.

32.—LEVEL SECTIONS (Earthwork); HEIGHT, 0-60 Ft.

BASE OF ROADWAY, 20 Ft. SIDE SLOPES $\frac{1}{2}$ TO 1.

Note.—The last two columns enable us to use any other base than 20 ft.:
 Ex.—Given height, 18.1 ft.; roadway 22 ft. Then we have 1947.4+
 .33+0.74) = 2081.5 cu. yds.

[Cu. Yds. per 100-Ft. Station.]

Add for Tenths of Feet in Height.

P. P.
7.41

Use with preceding column only.

33.—LEVEL SECTIONS (Earthwork); HEIGHT, 0-60 Ft.

BASE OF ROADWAY, 20 Ft. SIDE SLOPES 1 TO 1.

Note.—The last two columns enable us to use any other base than 20 ft.:

Ex.—Given height, 54.7 ft.; roadway 21 ft. Then we have, $15134 + \frac{1}{2}(400.00 + 5.19) = 15337$ cu. yds. (For Ht. > 60 ft., see Tables 28, 40.)

[Cu. Yds. per 100-Ft. Station.]

	Ht. Ft.	.0	.1	.2	.3	.4	.5	.6	.7	.8	.9	Width of 2 Ft. Cu. Yds	
Note that Base, Slope, and Cu. Yds. in this table may all be multiplied by the same factor; thus, using factor of $\frac{1}{4}$ for height of 34 ft., we have, 8500 cu. yds. for base of 25 ft. and slopes $\frac{1}{4}$ to 1.	0		7.4	15.0	22.6	30.2	38.0	45.8	53.7	61.6	69.7		Add for Tenths of Feet in Height.

Note that Base, Slope, and Cu. Yds. in this table may all be multiplied by the same factor; thus, using factor of $\frac{1}{2}$ for height of 45.1 ft., we have, 6105 cu. yds. for base of $\frac{1}{2}$ to 1.

Add for Tenths of Feet in Height.

P. P.
7.41

Use with preceding column only.

38.—LEVEL SECTIONS (Earthwork); HEIGHT., 0-60 Ft.

BASE OF ROADWAY, 28 Ft. SIDE SLOPES, $1\frac{1}{2}$ TO 1.

NOTE.—The last two columns enable us to use any other base than 28 ft.:
 e.—Given height, 33.6 ft.; roadway 30 ft. Then we have, $9756.4 + 4 + 4.44 = 10005.3$ cu. yds. (For Ht. > 60 ft., see Tables 24, 41.)

[Cu. Yds. per 100-Ft. Station.]

Add for Tenths of Feet in Height.

P. P.
7.41

Use with preceding column only.

39.—LEVEL SECTIONS (Earthwork); HEIGHT, 0-60 Ft.

BASE OF ROADWAY, 30 Ft. SIDE SLOPES, 1 to 1.

Note.—The last two columns enable us to use any other base than 30 ft.:

Ex.—Given height, 41.1 ft.; roadway 32 ft. Then we have, 10823+ (803.70 + 0.74) = 11127 cu. yds. (For Ht. > 60 ft., see Tables 28, 40.)

[Cu. Yds. per 100-Ft. Station.]

60	20000	20056	20111	20167	20223	20279	20335	20391	20447	20503	444.44	

Note that Base, Slopes, and Cu. Yds. in this table may all be multiplied by the same factor; thus, using factor of $\frac{1}{2}$ for height of 36 ft., we have, 4400 cu. yds. for base of 15 ft. and slopes $\frac{1}{2}$ to 1.

Add for Tenths of Feet in Height.
P. P.
Use with preceding column only.

40.—LEVEL SECTIONS (Earthwork); HEIGHT, 60-100 Ft.

BASES OF ROADWAY, 14-30 Ft. SIDE SLOPES, 1 TO 1.

Note.—The last two columns enable us to use any other base than given:
 Ex.—Given height, 71.5 ft.; roadway 32 ft. Then we have, 26879 + 530
 27400 cu. yds. (See also Table 28.)

[Cu. Yds. per 100-Ft. Station.]

41.—LEVEL SECTIONS (Earthwork); HEIGHT, 60-100 Ft.

BASES OF ROADWAY, 14-30 Ft. SIDE SLOPES, $1\frac{1}{2}$ to 1.

Note.—The last two columns enable us to use any other base than given:
 Ex.—Given height, 68.5 ft.; roadway 32 ft. Then we have, $33679 + 507$
 = 34186 cu. yds. (See also Table 24.)

[Cu. Yds. per 100-Ft. Station.]

	Ht. Ft.	Width of Roadway in Feet.									Width of 2 Ft. of 10 Ft. Cu. Yds. Cu. Yds.

Note that Base, Slope, and Cu. Yds. in this table may all be multiplied by the same factor. See side-notes to preceding tables.

Slope-Staking is one of the first operations after the location has been adopted and filed with the proper authorities to secure condemnation rights.

It consists of setting slope-stakes at points where the side slopes of cut and fill intersect the ground line; and embraces also, in its widest sense, intermediate cross-sectioning as shown in Fig. 19. The illustration shows the "grade rod" method, which is considered the best. The "grade rod" is the difference in elevation between the height of instrument and the top of fill or bottom of cut, for the station at which slope stakes are to be set; and is used directly with ground-rod readings.

Fig. 19.

For the station at which slope stakes are to be set; and is used directly with ground-rod readings. Thus, for the left-hand slope stake, $10.2 + 2.3 = 12.5$ = distance below top of roadbed and is marked -12.5. The "distance out" (from center line stake)

responding to -12.5 is $12.5 \times 1\frac{1}{2} + 7.0 = 25.8$. Hence $\frac{-12.5}{25.8}$ is the position

of the slope stake. Sometimes two or three trials have to be made to get the point which will give the proper relation between elevation, and distance from center.

The field notes are kept as shown at the bottom of sketch, Fig. 19; on the right-hand page of the note book, under *Left - Center - Right*. The left-hand page are *Station, Grade Elevation, + S., H. I., - S., B. M.* and *Grade Rod*, if the complete records of bench marks and turning points are

* Sometimes, however, the records of the turnings are kept on loose sheets and thrown away and the balance of the above notes, including the section notes, are all on the left-hand page, with an added column *Ground Elevation*; the right-hand page being reserved for office notes of quantities in excavation (including solid rock, loose earth) and embankment. The first named method is the best as it is a complete record of all field operations. The office copy may be in the form last mentioned; and it is best to copy the field notes every day as record.

Network Computation from cross-section notes as in Fig. 19, is made by cutting the figure up into triangles, rectangles and trapezoids, and can be calculated directly from the field notes. Thus, the area of the

right half of the figure = $\frac{16.0}{2} \times (26.2 - 7.0) + 7.0 \times \frac{16.2 + 16.4}{2}$. In this

note that the intermediate cross-section is taken 7.0 ft. out from one-half width of roadbed, a wise thing to do where practicable and an intermediate elevation is necessary) as it simplifies office work. On the left-hand side this was not done and we have for area

left half of figure: $11.0 \times \left(\frac{15.4 + 16.4}{2} \right) + 14.8 \times \left(\frac{15.4 + 12.5}{2} \right) - 12.5 \times$

(7.0) . The deduction is for the triangle outside the slope at T, as

included in the previous quantities. Fig. 17, page 1016, presents the form of sketch for computation and this will obtain when only the cut or fill is given in addition to the slope-stake notes. Thus, area

$D + d$, and area $c + d = \frac{10}{2}(H + h)$.

Section is called a "three-level"

Prismoidal Formula and Prismoidal Formula are used for the determination of the volume of prismoids, where the method as above will not suffice. The prismoidal formula is based on the "three-level", Fig. 20.

Fig. 20.

n = the number of the station, as 1095 + 50; *Grade Elevation* = elevation of sub-grade, i. e., bottom of cut or top of fill; $+S$ = back-sight rod reading on the bench mark (B. M.) to determine the height of instrument (H. I.); $-S$ = fore-sight, or the rod reading to determine the elevation of the turning point (T. P.) or B. M., from the H. I.

42.—PRISMOIDAL CORRECTIONS* $\left[-\frac{100}{12 \times 27}(H-h)(D-d)\right]$.
[Cu. Yds. per 100-Ft. Station.]

Note.— H , h , D and d are in feet.

* Correction to be subtracted when $(H-h)(D-d)$ is positive. (Usual.)
added " " " negative. (Rare.)

Correction for Curvature, in earthwork computation, is very often neglected. Let A , Fig. 21, be the total area of the cross-section at any station on a curve; d_A the horizontal distance from the center of the section to the center of gravity of A ; R the radius of the curve. Then the correction for curvature may be embodied by using a new area, $A_c = A \left(1 \pm \frac{d_A}{R}\right)$, and maintaining the distance between stations

Fig. 21.

as measured on the center line; $\frac{d_A}{R}$ to be added

if R_A , the radius to the center of gravity of A , is greater than R , and subtracted if $R_A < R$. This is based on the theory that the volume of a solid of revolution is equal to the area revolved multiplied by the length of the path traced by its center of gravity. From this, we have, Volume for one station $= A \times 100 \left(1 \pm \frac{d_A}{R}\right)$; but this is clearly equal to $100 A_c = 100 A \left(1 \pm \frac{d_A}{R}\right)$. In one case the length of station is maintained while the area of the section is considered to be increased or decreased; in the other case the reverse is assumed.

"Haul" is a term applied to the average "lead" or horizontal distance between the centers of gravity of the same material "in place" and "in fill." In Fig. 22, let $G. L.$ be the grade line, H the haul, $F. H.$ the free haul, and $O. H.$ the overhaul or paid haul. Then, overhaul = haul - free haul. The free haul may be 500 ft. more or less, according to the specifications and contract. The centers of gravity are determined after the division lines d are fixed, from the estimated quantities, in much the same way as the center of gravity of A , Fig. 21, was determined. "Shrinkage" is a refinement which may be considered if the quantities are large. "Waste" and "borrow" will affect haul, and notes should be made (on the profile) of the manner in which all material on the work has been handled.

Fig. 22.

Roadbed.—The standard roadbed cross-sections should be adopted before the grade line is established, in order to equalize cuts and fills, where

Fig. 23.

necessary, during construction. Each road has its own standard or rather standards, for the cross-section varies with the amount of traffic, height of embankment, whether on tangent or curve, main or branch line, etc. Fig. 23 shows about the minimum width of roadway that should be considered, namely, 14 ft. and 18 ft. at sub-grade for embankment and excavation, respectively. These should be increased rather than diminished, especially if on the main line, with high embankment, on a long curve, under heavy traffic. The width of roadway in embankment on existing roads varies from 12 ft. (minimum for cheap roads) to 20 ft. Allowance must be made for shrinkage of embankment as the width of roadbed at sub-grade will narrow three times the amount of vertical shrinkage, when side slopes are $1\frac{1}{2}$ to 1. For double track lines the roadbed for single track is increased by the distance between track centers, say 13 ft. The size of ditches in cuts will depend on the length of cut, amount of drainage, and slope of ditch. Drain tile should be placed below the frost line.

$$* A = a_1 + a_2 + a_3 + a_4; \text{ and } d_A = [a_2(d_1 - d_2) + a_3(d_1 + d_3) + a_4(d_1 + d_4)]A - d_1.$$

Rails and Fastenings.—Rails are rolled usually in 30-ft. lengths, although 33-ft. rails have lately been introduced on main-line track. Shorter lengths, varying by two feet, or even by one foot, are furnished for pre-serving "opposite" or "broken" joints in track laid on curves, and for switch "leads," etc. Rails are designated by the "weight per yard," as 60-lb., 70-lb., 80-lb., etc. For instance, a 30-ft. 80-lb rail will weigh 800 lbs. In order to decrease the number of existing standard rail sections and the consequent expense in rolling, as well as to improve the type and facilitate quick delivery from the mills, the Am. Soc. of C. E., in 1893, adopted a standard type called the "American Society Standard," shown in Fig. 24 and in Table 43, following.

Splices for rail joints have developed from the primitive "chair" which simply gave vertical support to the rail joint placed directly over the tie, to the "fish plate" (invented in the early 40's) which gave vertical stiffness to the joint (see Fig. 27, below), and later to the "angle bar" which gives lateral as well as vertical stiffness to the joint. Many improved forms of angle bars have appeared on the market from time to time, but only those of uniform cross-section, that can be rolled continuously, have become standard. Figs. 24, 26 and 28 show standard types.

Bolts for fastening the splice bars to the rail are often provided with lock-nuts to prevent the bolts from working loose, or at least from working loose too rapidly. One of the simplest and perhaps most common forms is a steel ring of square or hexagonal section cut beveled with sharp corners and forming a complete spiral curve of one turn. This is placed on the bolt and when the nut is screwed on, the spiral form of the lock-nut is compressed to a nearly circular form, and the sharp points pressing against the steel on either side prevent the nut and bolt from loosening. Weights and dimensions of splice bolts are given in Table 43.

TABLE 43, giving standard dimensions of rails, splice plates and bolts, will be found on the two following pages. The accompanying illustrations, Figs. 24, 26 and 27, are also a part of this table, as per references given therein. Fig. 24 is the Am. Soc. C. E. Standard rail section (see pages 1061-2). Figs. 26 and 27 are Penn. Steel Co. standards (see page 1062). Figs. 25 and 28, with tables of dimensions, will be found on pages 1061 and 1062, respectively.

For Rails 12 to 45 lbs. per ft.: A=2" B=4"

" " 50 lbs. and over: A=3 $\frac{1}{4}$ " B=5"" " 50 lbs. and over: A=1 $\frac{1}{4}$ " B=5" C=6"

43.—STANDARD DIMENSIONS OF RAILS AND FASTENINGS.—Concluded.

Adapted from Penn. Steel Co. (P. S. C.).

PART II.—Splice Plates. Note.—Splice Plates in table are adapted to Am. Soc. C. E. Standard Rails.

[illegible]

For Figs. 24, 26
and 27, see
page 1060.

Plg. 2A.

Wt. of Rail, Lbs.	Length, Feet	D	E	F	G	H	I	J	K	L
12 to 45.....	18"	4	4"	4 1/2"	4"		1 1/2"	1 1/2"	1 1/2"	3"
45 to 60.....	24"	4	4"	4 1/2"	4"		1 1/2"	1 1/2"	1 1/2"	3 1/2"
60 and over.....	30"	4	4"	4 1/2"	4"		1 1/2"	1 1/2"	1 1/2"	3 1/2"

For Single Track, the number of 30-ft. rails required per mile of track $\frac{2 \times 5280}{30} = 352$; of 33-ft. rails, 320; of 50-ft. rails, 211.2. The number of short tons (of 2000 lbs.) per mile of single track $= 1.76 \times \text{wt. in lbs. of single rail per yd.}$; thus, there are required 176 short tons of 100-lb. rails per mile of single track. The number of long tons (of 2240 lbs.) per mile of single track $= \frac{1}{4} \times \text{wt. in lbs. of single rail per yard.}$; thus, there are required 157½ long tons of 100-lb. rails per mile of single track. For 90-lb. rails, mult. 176 and 57½, respectively, by $\frac{9}{10}$; for 80-lb. rails, mult. by $\frac{8}{10}$; etc.

44.—WEIGHT OF RAILS PER YARD REDUCED TO TONS PER MILE OF SINGLE TRACK.

(Short tons at 2000 lbs.; long tons at 2240 lbs.)

Wt. per ard. Lbs.	Short Tons per Mile.	Long Tons per Mile.	Wt. per Yard. Lbs.	Short Tons per Mile.	Long Tons per Mile.	Wt. per Yard. Lbs.	Short Tons per Mile.	Long Tons per Mile.
8	14.08	12¼/7	56	98.56	88	76	133.76	119¾/7
12	21.12	18¾/7	57	100.32	89¼/7	78	137.28	122¾/7
16	28.16	25½/7	60	105.60	94¾/7	80	140.80	125¾/7
25	44.00	39¾/7	62	109.12	97¾/7	85	149.60	133¼/7
30	52.80	47¼/7	64	112.64	100¾/7	90	158.40	141¾/7
35	61.60	55	65	114.40	102¼/7	95	167.20	149¾/7
40	70.40	62¾/7	68	119.68	106¾/7	100	176.00	157¼/7
45	79.20	70¾/7	70	123.20	110	105	184.80	165
50	88.00	78¾/7	72	126.72	113¾/7	110	193.60	172¾/7
52	91.52	81½/7	75	132.00	117¾/7	120	211.20	188¾/7

Note.—Values in above table are exact. Fractions of long tons may be reduced to decimals of long tons and to pound equivalents as follows: ¼ = 14286 l. t. = 320 lbs.; ⅓ = 0.28571 l. t. = 640 lbs.; ⅔ = 0.42857 l. t. = 960 lbs.; ¾ = 0.57143 l. t. = 1280 lbs.; ⅞ = 0.71429 l. t. = 1600 lbs.; ⅞ = 0.85714 l. t. = 1920 lbs.

Middle Ordinates for "bending" (curving) rails, to be laid on curves, be obtained from the following formulas:

$$- \frac{L^2}{8R} \text{ (practically exact); or, } M' = \frac{.001L^2D}{9 \times 5} \text{ (nearly exact).....(1)}$$

$$- \frac{3L^2}{2R} \text{ (practically exact); or, } M'' = \frac{.004L^2D}{3 \times 5} \text{ (nearly exact).....(2)}$$

in which M' = middle ordinate to the curved rail, in feet;

M'' = middle ordinate to the curved rail, in inches;

L = length of rail in feet;

R = radius of curve in feet;

D = degree of curve in degrees and decimals.

Note that in the above formulas either the radius or the degree of curve may be used, both being exact for the flat curves, say up to 4° or 5°. For a 10° curve, the "radius" formula gives $M' = 0.196$ (exact); the "degree of curve" formula gives $M' = 0.200$ (2% large); same for 20° curve gives $M' = 0.391$ and $M' = 0.400$, respectively, instead of the correct value. For shorter rails the errors decrease, hence it is that either formula may be used for all practical purposes.

45.—MIDDLE ORDINATES IN INCHES FOR CURVING RAILS.

(Degrees of curve and radii are for 100-ft. chords.)

For Ordinates in Feet, see Table 46.

Note.—Ordinates are practically proportional to the square of length of rail. Thus, for 60-ft. rail, mult. value for 30, by 4; for 45-ft. rail, mult. value for 30, by $2\frac{1}{2}$; for 8-ft. rail, divide value for 16, by 4; etc.

[Middle Ordinates, in Inches.]

Degree of Curve.	Radius, Feet.	Length of Rail, or Arc, in Feet.

Note.—For reduction of inches and fractions to decimals of a foot, see Table 10, page 223. No particular refinement is necessary in curving rails: ordinates to the nearest $\frac{1}{4}$ " are close enough, usually.

The quarter ordinates are practically three-fourths the middle ordinate.

46.—MIDDLE ORDINATES IN FEET FOR CURVING RAILS.

(Degrees of curve and radii are for 100-ft. chords.)

For Ordinates in Inches, see Table 45.

Note.—Ordinates are practically proportional to the square of length of
 Thus, for 60-ft. rail, mult. value for 30, by 4; for 45-ft. rail, mult.
 ie for 30, by $2\frac{1}{4}$; for 8-ft. rail, divide value for 16, by 4, etc.

[Middle Ordinates, in Feet.]

Rad- ius. Feet.	Length of Rail, or Arc, in Feet.

Note.—For reduction of decimals of a foot to inches and fractions, see
 ie 10, page 223. No particular refinement is necessary in curving rails:
 nates to the nearest $\frac{1}{4}$ " are close enough, usually.

The quarter ordinates are practically three-fourths the middle ordinate.

47.—CHORD LENGTHS OF CURVED RAILS.
(Degrees of curve and radii are for 100-ft. chords.)
[Chord Lengths, in Feet.]

Degree of Curve.	Radius. Feet.	Length of Rail, or Arc, in Feet.

Note.—For reduction of decimals of a foot to inches and fractions, see Table 10, page 223.

TO FIND THE DEGREE OF CURVATURE OF LAID TRACK.

(See Formulas 1 and 2, and Notation, page 1063.)

On maintenance work it is often necessary to find the degree of curvature of laid track, on a curve which has been more or less shifted and deranged by the trackmen; and then to run in a regular or a spiral curve which will best fit the existing track: so as to require the least possible shifting of the latter.

From the approximate formulas (1) and (2), page 1063, it will be seen that there are direct ratios between the degree of curve (D), the curved length of rail (L), and the middle ordinate (M). If D is in degrees, and L and M in feet, we have, by transposition,

$$D = \frac{45000 M}{L^2} \text{ (approximate) } \dots\dots\dots (3)$$

For a 100-ft. length of rail, $L=100$, hence,

$$D = 4.5 M \text{ (approximate) } \dots\dots\dots (4)$$

$$= 4.58 M \text{ (nearly exact) } \dots\dots\dots (5)$$

For a 30-ft. length of rail, $L=30$, hence,

$$D = 50 M \text{ (approximate) } \dots\dots\dots (6)$$

$$= 51 M \text{ (nearly exact) } \dots\dots\dots (7)$$

For a 21' 3" length of rail,

$$D = \text{the middle ordinate in hundredths of a foot.} \dots\dots\dots (8)$$

i.—MIDDLE ORDINATES FOR 20- AND 30-FT. CHORDS AND 30-FT. ARCS.

ALSO, CHORD LENGTHS OF 30-FT. ARCS.

e.—Radii are given in feet and tenths; other dimensions in feet (') and inches (").

Ordinates for 30-ft. arcs, down to 150-ft. radius, are practically the same as for corresponding 30-ft. chords.

"Shims" are pieces of wood or iron inserted at rail joints when track is laid, in order to give the proper spacing of joint. The thickness of the shim depends upon the temperature. A good rule for thickness of shim is the following:

$$S = .00128 L (T - t)$$

in which S = thickness of shim, in 16ths of an inch;

L = length of rail, in feet;

T = "hottest" temp. to be expected in that locality, in degs. F.

t = prevailing temp. when track is laid, in degs. F.

The Suspended Joint (i. e., where the joint comes between two supporting ties) has practically superseded the "supported" joint which rests directly on a single tie with the usual spacing. But better still, by far, is the use of three ties closely spaced at each joint with angle- or splice bars long enough (say 3½ to 4 ft.) to get direct support from the two outside ties. Such an arrangement may properly be called a 3-tie "supported" joint.

Alternate, Staggered or Broken Joints are usually preferred on main line to the "opposite" or "even" joints. The advantages of "broken" joints are: (1) The intensity of shock due to passing trains is reduced about 50% although the number of shocks is doubled; (2) the track can be kept in better surface and line on tangents; (3) on curves, one line of rails stiffens the other at the joints and aids in preserving uniform curvature even if the rails were not curved properly prior to laying. The advantage of "opposite" joints is purely one of cost in tracklaying, and hence for second-class yards, or for slow train service generally, they may do.

Cross Ties.—Ordinary track ties are usually 8 or 8½ ft. long; bridge ties or single track, 12 ft.; and switch ties, up to 15 ft. or more in length.

Tables 50 and 51, respectively, give the number of cubic feet and feet board measure in ties of various dimensions.

Tables 52 and 53 are bills of switch ties for No. 6 and No. 8 frog, respectively. To find the bill of material for any other frog: Draw the switch to ale, and scale off the lengths of ties. (For turnouts and switches, see page 1075.)

50.—CUBIC FEET IN WOODEN TIES OF VARIOUS DIMENSIONS.

Total lin. ft. in above bill, using exact lengths = 494 lin. ft.

Total lin. ft. in above bill, using 1-ft. lengths = 506 lin. ft.

"Winter cut" ties are the best, and hewed ties are better than sawed. Planing improves sawed ties in shedding water and preventing decay. Creosoting lengthens the life of ties, and the creosote oil in ties so preserved has a beneficial effect on spikes in preventing rust.

Wooden ties are the only kind used to any great extent in the United States at the present time. The old stone* tie has been abandoned. When the wooden tie is supplanted it will probably be by the steel tie, the steel-concrete tie, or the steel-paper tie; and then only gradually and on roads of the first class.

Oak ties are the best, and white oak is the best variety as it holds the spikes better. The other varieties frequently used are bur oak, post oak, hestnut oak and red oak. Together they comprise at least one-half of the total number of ties in use. The average life of the best oak tie is about eight years, varying inversely with the humidity of the atmosphere, and depending upon the amount of traffic, position in the track (whether on curves or tangent), etc. Chestnut ties will last about as long as oak but do not hold a spike as well. Cedar ties are the longest lived, but they do not wear well under heavy traffic unless tie-plates are used, in which case they will last about twice as long as oak. Red cedar is not now readily obtainable, white cedar being much more plentiful. Next to oak, the various varieties of pine furnish most of the ties now being used: Yellow pine, in the South and East; loblolly pine in the Southwest; California mountain pine, Oregon pine (Douglas fir or Washington pine), on the Pacific Coast; Michigan pine in the Northwest; etc. In the New England States, hemlock and spruce are much used, although inferior to the Southern yellow pine. Black walnut is used in the middle West, and redwood in California. The life of redwood is about up to that of cedar if tie-plates are used, the wood being very soft.

Tie Plates are used on wooden ties, particularly those of soft wood, to prevent the rails from cutting into them; otherwise the life of such ties will be measured by the amount of heavy traffic passing over them, rather than by their resistance to the action of the weather, etc. The life of soft ties, then, may be increased: (1) by creosoting, to resist the action of the weather, as already explained; (2) by the use of tie plates, to resist abrasion.

The usual construction of tie plates consists simply of flat, plain or beveled plates say 6" x 8", with bottom lugs or flanges say $\frac{1}{4}$ " deep, which are driven into the tie. The plate is provided with 2, 3 or 4 square holes gaged to the rail flange, for spiking. In the earlier patterns there were lugs above the plate on one or both sides of the rail flange, but in more recent designs these are omitted. Figs. 30 to 33 show types of the Servis, Walhauper, Fox and Diamond tie plates.

Fig. 30.

Fig. 31.

Fig. 32.

Fig. 33.

The thickness of metal may vary from $\frac{1}{16}$ " to $\frac{1}{4}$ ". The cost of tie plates is very nominal, varying from 5 to 15 cents each. They are used generally at main points instead of universally, as at rail joints, where there is much hammering; on heavy grades where sand is much used; on expensive ties and switch ties; on curves; and in places generally where the cost of ties would be unusually expensive, as at stations and crossings, and in tunnels.

Rail Braces are designed to resist the outward lateral thrust of the rail when passing trains; hence they are placed on the outside of rail, pressed against it, and spiked solidly to the ties. The most primitive form of brace, and one which may be seen in almost any yard, at switches, is

one ties were tried in the early days on the Boston & Worcester R. R. (part of the B. & A. R. R. system) but were abandoned on account of their cost and also because they did not furnish a sufficiently elastic base.

a bent fish-plate with one end pressing against the web of the rail, just under the head, and the other end spiked to the tie. Many patterns are made of cast iron or cast steel. Fig. 34 shows the Alkins brace of forged steel; and Fig. 35 shows the Edwards brace, being a combination rail brace and tie plate. Rail braces are used on curves and at switches, and in general where double spiking is insufficient.

Fig. 34.

Fig. 35.

Steel Ties are much used in Europe and somewhat in the United States, but are at present avoided here on account of the expense as compared with wooden ties. Those in Europe are generally of the trough type. Figs. 36, 37 and 38 show a special I-beam section, after the original design of Mr. C. Buhner, roadmaster of the L. S. & M. S. Ry., and manufactured by the Carnegie Steel Co., for the Bessemer & Lake Erie Ry. The tie is 8' 6" long and weighs 19.36 lbs. per ft. Section A-B of Figs. 37 shows the depression lug 6" from ends of tie to prevent

lateral movement in the ballast. Figs. 38 show details of rail fastenings, including those at joint where angle splice bars are used.*

Concrete-Steel Ties may be said to be in the experimental stage. Those interested in these types may find designs of the †Campbell tie and the ‡Percival tie in *Eng. News*, Oct. 5, 1905, page 349.

* For full description, see *Eng. News*, Aug. 24, 1905, page 202.

† Mr. R. B. Campbell, Gen. Man., the Elgin, Joliet & Eastern Ry.

‡ Mr. H. E. Percival, Galveston, Tex.

Ballast may be broken stone, gravel, cinders, sand or dirt. The first named is by far the best and should be of about the size that will pass through a $2\frac{1}{2}$ in. ring. Most roads using a great amount of broken stone have their own quarries and rock-crushing plants instead of breaking the stone by hand. Portable stone crushers are also used. The advantages of broken stone and gravel over the finer materials are: (1) good drainage, (2) firm bearing and solid ballast packing for the ties; (3) absence of frost, (4) lack of retention of moisture to rot the ties, (5) freedom from dust, unpleasant to passengers and injurious to the wearing parts of the rolling stock.

For estimating the amount of ballast per mile of track, a sketch should be drawn of the ballast cross-section desired (see Fig. 23, page 1059) and from this deduct the cubic contents of the ties from Table 50, page 1069.

Thus from the figure, we have,

1. ft., gross, of ballast per lin. ft. of single track..... = 9.5
deduct for tie ($6'' \times 8''$ —8' spaced 24" centers) by table = 1.333

1. ft., net, of ballast per lin. ft..... = 8.167

1. yds. net of ballast per mile = $8.167 \times \frac{5280}{27} = 1597$.

Since 1600 cu. yds. of ballast per mile of single track is the very least that can be assumed. This is for a depth of 12 ins. and a top width of 8 ft. Generally the ballast is much deeper and wider, say 18" below top of tie, $\frac{1}{2}$ to 10 to 12 ft. wide.

Gage of Track and Wheels.—The *minimum* "Standard" Gage* of track in the United States and Canada (also in England and most European countries) is $4' 8\frac{1}{2}''$. On roads where this minimum gage is used for straight track, the gage is widened for track on curves, say about $\frac{1}{4}''$ per each degree of curvature, as per the following table.

54.—INCREASE IN GAGE FOR VARIOUS DEGREES OF CURVATURE.

(Based on about $\frac{1}{4}''$ per degree of curve.)

of ve.	1°	2°	3°	4°	5°	6°	7°	8°	9°	10°	11°	12°	13°	14°
in	$\frac{1}{8}''$	$\frac{1}{4}''$	$\frac{3}{8}''$	$\frac{1}{2}''$	$\frac{5}{8}''$	$\frac{3}{4}''$	$\frac{7}{8}''$	$1''$	$1\frac{1}{8}''$	$1\frac{1}{4}''$	$1\frac{3}{8}''$	$1\frac{1}{2}''$	$1\frac{5}{8}''$	$1\frac{3}{4}''$

On some roads in the U. S., mostly in the South, the "Standard" Gage is $9''$. This is true also of some main-line freight tracks on the P. R. R. m. In such cases the gage is seldom widened for ordinary curves. There is also another "Standard" Gage employed by a very few roads, $4' 8\frac{1}{2}''$, which may be considered to be a compromise between the two above mentioned.

Fig. 39 shows the Master Car Builders' (M. C. B.) standard wheel (and gage, which has become universally standard. Note that the side

Fig. 39.

the wheels is $\frac{1}{4}''$ for a $4' 8\frac{1}{2}''$ gage, and that for a $4' 9''$ gage it would be to $\frac{1}{2}''$.

Gage of track is the distance between "inside heads," or "gage sides,"

The following data regarding gages will be found useful in connection with the calculation of turnouts, switches, crossovers, crossings, etc.

Various Track Gages are used in different countries as follows: In the United States, Canada, England and most European countries, the standard gage is 4' 8½" = 1.435 meters. This is true of Austria, Switzerland, Germany, France, Hungary, Italy, Sweden, and Balkan. In Russia, the standard gage is 1.524 meters with the exception of the Warschau-Wien and Warschau-Bromberg which have a standard of 1.435 meters. In Spain, the standard is 1.676 meters, and this gage also prevails mostly in the East Indies, Argentine and Chile. It corresponds to the old English gage of 5' 6". The gage of the Great Western R. R. in England, was changed from 7 ft. (in connection with 4' 8½") wholly to standard gage in 1890. In Ireland, the standard gage is 5' 3". Narrow gages are used in many countries. In Norway, Cape Colonies, South Australia, Japan and Java, a gage of 3' 6" is used largely. In Brazil, Algiers, Greece and Corsica, 1 meter is common. Gages of 1 meter, 0.75m. and 0.60m. are used to some extent in Germany for narrow gage extensions, etc. Many roads in Switzerland are of 1m. gage. The gage of the Festiniog-Bahn, in Wales, is only 0.591 meter.

The "Best" Standard Gage, for universal inter-traffic, has gradually sifted down to that of about 4' 8½". Wide gages of 5 to 6 ft., and narrow gages of 3 to 3½ ft., have been changed to the above standard almost universally throughout North America, and the chances are that the same standardization will prevail ultimately in South America also. Pertinent to this question, the writer has lately been of the opinion that, with the enormous locomotives now being built, and with the limited head room, a wider gage, say 5' 3" to 5' 6" would have been a better standard to adopt than the present one. From the standpoint of the locomotive manufacturer, the following letter, under date of September 8, 1906, from the Baldwin Locomotive Works, Burnham, Williams & Co., of Philadelphia, in reply to a query from the writer, is interesting:

Your favor of September 4th was duly received.

The capacity of any railway, as an instrument for transportation of goods, is proportionate to its gage. In fact, the practicable weight of locomotives and the practicable capacity of cars, increase directly in proportion to increased width of gage. In designing some of the heaviest locomotives now required for freight traffic, it would be a great comfort if the gage were wider than 4' 8½". As a broad proposition, however, we do not think that even the congestion of traffic upon the principal trunk lines has yet reached a point limited by the size of locomotives, nor that wider gage than 4' 8½" has generally become necessary.

Turnouts and Switches.—A turnout (for switching trains from one track to another) consists essentially of a switch, a frog, and the connecting "lead" rails.

Switches may be classed under three main heads, namely, the stub-switch, the split-switch, and the Wharton switch. Where there is a double turnout from the same track, the diverting switch is called a three-throw switch. Fig. 40 shows a double "slip" switch, very useful in switching-yards

Fig. 40.

or economizing room, and particularly adapted to sharp crossings, with interchangeable traffic. For instance, a train may pass from either track on one side of the crossing to either track on the other, by operating the switches *s*. In the Fig., the switches are set for "crossing traffic" on tracks *a* and *Bb*. It is to be noted that the outside curved rails *c* are continuous throughout. The letters *F* denote position of frogs; and *P*, the points of vitches. A single slip switch has but one curved rail *c* with its corresponding gage rail, instead of two as shown in Fig. 40.

Frogs are devices for allowing the flanges of wheels to pass unobstructed along one rail crossing another rail. There are three distinct classes, namely, stiff or rigid frogs, spring or spring rail frogs, and movable-point frogs.

Stiff frogs may be made up of rail sections, or of solid steel castings. Fig. 41 illustrates the shape of a stiff rail frog, the heads of rails only being

Fig. 41.

m. *LW* and *RW* are left- and right-wings respectively; and *MP* and *SP* are main- and side-points. Note that the "point of frog" is at the section of the outside lines of *MP* and *SP* and a little beyond the blunt tip of tongue. All frogs are designated by numbers. Thus, if we let *L* be the length from point of frog to heel, and *W* equal the width at heel,

$$\text{"frog number"} = \frac{L}{W} \dots \dots \dots (1)$$

range from numbers 4 to 24, but the usual limits are 6 and 12, while 9 are perhaps the most common. We will show further on how the number determines practically the radius or degree of the turnout and it will be seen also what bearing the kind of switch and length of

ave on the problem, for any particular gage of track. **Cast manganese steel frogs** will greatly outwear the ordinary rail way about 9 to 1, while they cost about 4 or 5 times as much. They are had "one-sided" or "double sided" depending on whether the heavy is mainly on one track, or is "balanced." There is a saving in cost of 25% in favor of the former.

Spring Rail Frogs are usually placed on the main line because there is no shock in riding over them, as there is over the rigid frogs. Fig.

P. & R. Railway standard, showing the right wing *RW* pressed against the tongue by the spring, thus forming practically a con-

s the ratio $L+W$ is constant for any given frog, its number may be determined by measuring the distance L' , from the theoretical point to a point where W' = say 4"; then $n = L' + 4$.

56.—PROPERTIES OF FROG ANGLES ϕ —

WITH LOGARITHMIC VALUES.

Note.—Logarithmic values are exact for the given frog numbers; the frog angles are to the nearest second. (Angles to the nearest minute are close enough, usually.)

For values of cosec ϕ and cot ϕ , see Table 64.

Part I.—Properties of Frog Angles, ϕ .

Log sec ϕ = colog cos ϕ = 1 (or 11) - log cos ϕ .
Thus, log sec 14° 15' 00" = 0.013728.

$$\text{Vers } \phi = \sin \phi \cdot \tan \frac{\phi}{2} = 2 \sin^2 \frac{\phi}{2}.$$

tinuous main line rail. When a train takes the *SP* rail, the *RW* is crowded open by the wheel flange, but springs back after the train has passed. Spring-rail frogs are "rights" and "lefts" and hence care must be used in ordering them. Other types are the Vaughan, Wood, Ajax, Eureka, etc. Double spring rail frogs are seldom used.

Fig. 42.—Spring Rail Frog.

Movable-Point Frogs are shown in Fig. 43, as manufactured by Wm. Wharton, Jr., & Co., Philadelphia. Note that this type might well be used in Fig. 40 at the central frogs *F*. The cut is self-explanatory. The movable points also may be of manganese steel if required.

Log sec $\frac{\phi}{2}$ = $\text{colog cos } \frac{\phi}{2}$ = 1 (or 11) - log cos $\frac{\phi}{2}$.
Thus, log sec 7° 07' 30" = 0.0033667.

$$\text{Vers } \frac{\phi}{2} = \sin \frac{\phi}{2} \cdot \tan \frac{\phi}{4} = 2 \sin^2 \frac{\phi}{4}.$$

Fig. 43.

Crossing Frogs are usually rigid, and made up of rail sections with perhaps cast steel frog junctions. There is a form of movable frog consisting of short pieces of rail on miniature turntables that can be turned in any desired direction, thus making a continuous rail of either track.

Stub Switches.—The stub switch is the cheapest and most primitive form. Its use is now confined to second-class yards and spur connections with sidings, having disappeared entirely from main yards. It should never be used for main line connection. Fig. 44 illustrates the essential features.

The head blocks *H B* are at the junction of the switch rails *S* with the main lead (rail) *M L* and turnout lead (rail) *T L*, which "lead" to the toe of frog; also with the continuous main line rail *M* and turnout rail *T*. The "throw" of the switch is clearly the distance between the gage sides of rails *M* and *T L* or *M L* and *T*, at the head blocks, and is usually 5, 5½ (or 6) ins.* The switch rails are tied together with a front rod and three or more back rods. The length of switch rails is governed by the frog number or by the degree of turnout curve. The following table was calculated by the author in 1887 while he was Resident Engineer of a western road and was used by the foremen in laying out all switches, including the terminal yards at Toledo. The sharpest frog was No. 9, and the table was used for both stub and split switches; but for frog numbers higher than 9 the table does not apply strictly to the latter. The virtue of the table lies in the offset distances between the gage sides of *M L* and *T L* rails, Fig. 44, as given in the last seven columns but one. These offsets are measured at points 10-, 20-, 30-ft., etc. from theoretical point of frog (Fig. 41). By this means the position of the *T L* rail is fixed quickly, and from it the *T* rail is gaged. The efficiency of the work per gang was increased from two switches in three days to one switch per day, in broken stone ballast.

REMARKS.—"Shortened" leads are generally used in practice as giving better line to the turnout curve, where high frog numbers are used. Where shortened leads are adopted, they are fixed to suit rail lengths without cutting.

* This last column gives the distance between points of frogs, measured along center line of main track.

58.—THEORETICAL (OR STUB) SWITCHES. GAGE, $8\frac{1}{2}$ "—Concluded.
(See Figs. 44, 45 and 46, pages 1078, 1082 and 1083.)

Turnout Curves for Stub Switches are simple curves. In staking them out on the ground it is necessary only to set two stakes, one marked *P. F.*,

Fig. 46.

opposite the point of frog, and the other marked *P. S.*, opposite the point of switch. They should be set on the frog side of the track to indicate the direction of the turnout. The *P. F.* is usually located about half a frog length from a rail joint to save one cut of rail. No refinement is necessary in the calculation of turnouts, and the following formulas may be used where the main track is straight, as in Fig. 46:

Let ϕ = frog angle = central angle of turnout curve;

n = frog number (see Fig. 41);

l = theoretical lead to point of main frog;

l' = theoretical lead to point of crotch frog;

g = gage of track;

R = radius of turnout curve;

s = switch length, *P. S.* to *H. B.*;

m = middle ordinate of turnout curve;

q = quarter ordinates of turnout curve.

t = throw of switch.

All distances in feet.

$$\text{Then, } \tan \frac{\phi}{2} = \frac{g}{l};$$

$$\cot \frac{\phi}{2} = \frac{l}{g} = 2n;$$

$$n = \frac{1}{2} \cot \frac{\phi}{2} = \frac{l}{2g} = \sqrt{R + 2g};$$

$$R = g + \text{vers } \phi - \frac{g}{2} = 2gn^2;$$

$$= l + \sin \phi - \frac{g}{2};$$

$$l = 2gn = g \cot \frac{\phi}{2} = \left(R + \frac{g}{2}\right) \sin \phi;$$

$$s = 2n\sqrt{gt} = \sqrt{2Rt};$$

$$t = s^2 + 2R;$$

$$m = g + 4 \text{ (nearly)};$$

$$q = \frac{3}{4}g + 4 = \frac{1}{4}s \text{ (nearly).}$$

All the above formulas may be used with perfect safety for field work. Other formulas may be deduced from these by transposing or equating.

Double Turnouts (=three-throw turnouts) require two main-line frogs and one crotch frog. If the two turnouts are opposite and of equal radii, then, Fig. 46, ϕ' , the angle of the crotch frog, is equal to double the central angle $\frac{\phi'}{2}$. But $\left(R + \frac{g}{2}\right) \text{ vers } \frac{\phi'}{2} = \frac{g}{2}$, hence vers $\frac{\phi'}{2} = \frac{g}{2} + \left(R + \frac{g}{2}\right)$, from which ϕ' is obtained.

Further, if n' = the number of the crotch frog,

and l' = the crotch frog (point) distance from the P. S., we have,

$$R = 4 n'^2 g \text{ (nearly)} = 2 n'^2 g;$$

$$n' = n + \sqrt{2} \text{ (nearly)} = 0.7071 n \text{ (nearly);}$$

$$l' = 0.707 l \text{ (nearly).}$$

Hence n' and l' are respectively equal to n and l multiplied by 0.707 (nearly). See Table 58.

Curved Main Track.—The above remarks apply to turnouts from straight main-line track, in connection with the stub switch. It is to be remembered that nearly all the formulas used in practical track work are approximate and close enough to the exact values, which may be obtained by trigonometric calculation. We will show now how the foregoing formulas may be applied to turnouts from curved main-line track. In order to illustrate we will consider Fig. 46 to be warped so the main line is curved instead of straight:

Let T° = degree of curve of turnout from straight track;

t° = degree of curve of turnout from curved main line;

M° = degree of curve of main line after curving.

Then $t^\circ = T^\circ + M^\circ$ when main line is curved toward turnout;

$t^\circ = T^\circ - M^\circ$ when main line is curved away from turnout.

For instance, a No. 9 frog calls for a $7^\circ 30'$ curve from a straight track; it calls for $10^\circ 30'$ curve from the *inside* of a 3° main-line curve; and for a $4^\circ 30'$ curve from the *outside* of a 3° main-line curve. Hence, when the two curves are in the same direction we have to find their difference, and when in *opposite* directions we have to find their sum, to get the degree of curve t° in Table 58, preceding, and the desired frog number, n , corresponding thereto.

Split Switches.—In our consideration of the stub switch, which is really for second-class track work, we have assumed all frogs in the turnout curves to be curved, whereas they are straight, and should be so considered in first-class track work where the split switch is used, although formerly this refinement was not considered necessary. This introduces a short tangent in the turnout at the point of frog. Moreover, split switch points are straight and it is now customary to take this fact into consideration in calculating the turnout curve, which really extends only from the heel of switch (P. C.) to the toe of frog (P. T.), joining the two short tangents above mentioned, instead of from point of switch to point of frog as assumed in Table 57, preceding.

The following is the practice of the Weir Frog Co., of Cincinnati, Ohio:

1.—TURNOUTS FOR SPLIT SWITCHES AND SPRING FROGS. GAGE 4' 8½".

FORMULAS FOR SPLIT SWITCHES.

(a).—Assuming Frog to be curved.

ion:

g —gage;

s —length of switch rail;

t —throw of switch;

α —switch angle;

β —frog angle;

R —radius of turnout curve;

$r = R + \frac{g}{2}$; l —lead.

in feet.

Fig. 51.

Formulas (Approximate):

$$\sin \alpha = \frac{t}{s};$$

$$l = s + \frac{g-t}{\tan \frac{1}{2}(\phi + \alpha)};$$

$$R' = \frac{g-t}{\cos \alpha - \cos \phi}.$$

(b).—Assuming Frog to be *Straight*.

Notation:

f = straight length of frog to *P. F.*, in feet.

Balance of notation as on preceding page.

Formulas (Approximate):

$$\sin \alpha = \frac{t}{s};$$

$$l = s + \frac{g-t-f \cos \phi}{\tan \frac{1}{2}(\phi + \alpha)} + f \cos \phi;$$

$$R' = \frac{g-t-f \sin \phi}{\tan \frac{1}{2}(\phi + \alpha)}.$$

Fig. 52.

Note.—Switches can be planned graphically very easily by drawing them to scale and scaling the dimensions. After the switch length and switch angle are drawn for one rail, the frog, with angle ϕ and length f , may be "slid" long the other "rail" until the semi-tangents, s and t , are equal.

Wharton Switch.—The virtue of the Wharton switch lies in the fact that no frog is necessary for a turnout curve from the main line, for which it is especially designed, and that the main line rails are therefore unbroken. Fig. 53 is a general plan of the switch as patented April 2, 1901, showing it in position for main-line traffic. The switch rails are on a grade, rising from the points, and when thrown over and set for the siding the wheels of the train ride up on them, clearing the flanges from the main track. The trip rail is pivoted so that when the switch is set for the siding, the end G of guard, nearest the point of switch, swings outward and hugs the main rail. Hence, a train coming heel on, on the main line, crowds the trip rail inward and throws the switch automatically, for the main line.

Fig. 53.—Wharton Switch. (See also Fig. 43.)

64.—LADDER TRACKS. SPACING OF FROGS.

(Any Gage.)

EXCERPTS AND REFERENCES.

Train Resistance Formulas (By J. G. Crawford. Eng. News, Oct. 31, 01).—Also diagrams of train resistance curves representing various formulas.

Holbrook's Spiral Curves (Eng. News, June 13 and Aug. 15, 1901).—Formulas and tables.

Transition Curves (By W. B. Lee. Trans. A. S. C. E., Vol. XLVI).

Gravity Yards, Switches and Frogs of the Chicago Transfer and Arling Co. (Eng. News, Jan. 2, 1902).—Illustrated.

The Weehawken Inclined Railway (By C. L. Duenkel. Eng. News, Jan. 16, 1902).—Illustrated.

The Rutland-Canadian Railway and Its Structures (By J. W. Burke. Eng. News, Jan. 15, 1903).—Illustrations of turntable machinery for swing gate, details of overhead steel highway bridge, masonry cattle pass, masonry box culvert, surface cattle-guard.

Largest Capacity Gondola Cars; Chicago & Alton Ry. (Eng. News, Dec. 26, 1903).—Illustrated. Capacity, 80,000 lbs.; weight, empty, 31,000 lbs.; length over end sills, 36 ft.

An Automatic Mine Car Tipples (Eng. News, May 21, 1903).—Illustrated.

Largest Freight Car in the World (Eng. News, July 2, 1903).—Illustrated. Capacity, 300,000 lbs.; weight, 196,420 lbs.; length of car over end sills, 103 ft. 10½ ins.

Steel Ties on Bessemer & Lake Erie R. R. (Eng. News, Nov. 5, 1903).—Illustrated.

Cost of Railway Ballast (W. C. Cushing. Eng. News, Mar. 31, 1904).—Record of experimental test of three different sizes of broken stone ballast on B. & O. Ry., with cost of each: Average costs per ft. of double track, \$1. to \$1.50.

A Conduit Electric Railway in London (Eng. News, April 21, 1904).—Illustrated.

Standard Girder-Rail Track Construction for City Streets, Penna. R. R. (Eng. News, Aug. 11, 1904).—Illustrated: Cross-section of rail, and details of track construction.

Screw Spikes for Railway Track (Eng. News, Aug. 25, 1904).—Illustrated: 7 forms of spikes, and machine for driving.

Reinforced-Concrete Ties, Ulster & Delaware Ry. (Eng. News, Oct. 6, 1904).—Illustrated.

Transfer Tables Without Pits and Traveling on Curves (Eng. News, Oct. 6, 1904).—Illustrated.

Cost of Electric Railway Power Production and Transmission in the State of Indiana (By A. S. Richey. Eng. News, Feb. 16, 1905).—Efficiencies: Step-up transformers, 94%; transmission lines, 97%; step-down transformers, 93%; rotary converters, 80%; direct-current distribution, 80%; combined efficiency, 54%.

The Cost for Concrete Fence Posts (Eng. News, Mar. 9, 1905).

The San Pedro, Los Angeles & Salt Lake Ry. (Eng. News, June 22, 1905).—Illustrations of standard roadbed cross-sections.

A Table of Turnout Curves and Crossings (By J. H. Milburn. Eng. News, July 13, 1905).—Including frog numbers 10, 12, 15, 16 and 20.

Some Records of Maintenance-of-Way Costs on American Railways (Eng. News, July 27, 1905).—Tables.

Concrete Ties on the L. S. & M. S. Ry. (Eng. News, Aug. 17, 1905).—Illustrated. (See, also, Eng. News of Oct. 5, 1905, for descriptions and illustrations of the Campbell and Percival ties.

Electric Equipment and Reconstruction of the New York Terminal Lines and Grand Central Station, N. Y., C. & H. R. R. R. (Eng. News, Nov. 16, 1905).—Numerous illustrations, with 2-page insert,

Switch Leads for Narrow-Gage Track (Eng. News, Dec. 7, 1905).—Tratman's formula.

Reinforced-Concrete Fence Posts (By P. L. Wormeley, Jr. Eng. News, Jan. 18, 1906).—Illustrations of posts, molds for making, wire attachment, etc.

Summit or Hump Yards for Gravity Switching (Eng. News, Mar. 22, 1906).—Illustrated.

Curving Rails by Power; Nashville, Chattanooga & St. Louis Ry. (By G. F. Blackie. Eng. News, May 31, 1906).—Illustration of mechanism.

Track Construction of Underground Railways (Eng. News, Aug. 2, 1906).—Illustrated.

A New Snow Scraper for Use on Locomotives (Eng. News, Aug. 9, 1906).—The Root scraper—illustrated.

Some Tables and Other Data for Railway Locating Engineers (By C. P. Howard. Eng. News, Sept. 13, 1906).—Formulas: Weights of bridges; spiral curves. Tables: Spiral curves; excavation tables, embankment tables; box culverts; areas for waterways; contents of retaining walls and abutments; weights of trusses, plate girders and viaducts; etc.

Track Construction for Railway Tunnels (Eng. News, Sept. 20, 1906).—Illustrated.

Devices to Keep Railroad Switches From Becoming Clogged With Snow and Ice (By F. G. Shaw. Eng. News, Oct. 18, 1906).—Two systems described: Gas heating, and oil heating.

Bumping Posts are illustrated and described in Eng. News, Oct. 25, 1906.

A Simplified Method of Laying Out Transition Curves (By T. A. Ross. Eng. News, Nov. 15, 1906).—Transition curve table suitable for speeds of about 30 miles per hour.

Wooden Ties Buried in Concrete, illustrated in Eng. News, Jan. 17, 1917. See, also, discussions of Jan. 31 and Feb. 7, 1907.

A Noise-Deadening Experiment on the Chicago Elevated Loop (Eng. News, Feb. 21, 1907).—Illustrated.

Tests of Holding Power of Railway Spikes (Eng. News, Mar. 7, 1907). Tests made by Mr. Roy I. Webber, Instr. of Civ. Eng., Univ. of Ill., and results are given in Bulletin No. 6, issued by the Experiment Station. New spikes and plain spikes; direct pull and lateral displacement.

A New System of Block Signaling on the P. R. R. (Eng. News, May 9, 1907).—Illustrated.

New Rails for the Chicago Street Railways (Eng. News, May 23, 1907).—Specifications. Illustrated section of 129-lb. grooved girder rail.

Experience With Wide-Base Rails on the A., T. & S. F. Ry. (Eng. News, June 13, 1907).—Illustrated section of 101-lb. rail, $5\frac{1}{2}$ " high and $6\frac{1}{2}$ " width of base. The rail was designed with the idea of giving a larger bearing upon the ties, and using it without tie-plates. The rail was not easy to handle, and the mills experienced great difficulty with it. The results are said to have been satisfactory as far as the effect upon the ties was concerned, but it has been found that the rails break very readily in the base. The rail joints have 20" splice bars, with four $\frac{1}{2}$ " bolts spaced 8" c. to c. These bars weigh about 75 lbs. per pair.

A New 100-lb. Rail Section (Eng. News, June 27, 1907).—Illustrated ($6\frac{1}{2}$ " high, and $5\frac{1}{2}$ " width of base). Table of dimensions of heavy rail compares this rail with the A. S. C. E. (100-lb.), Dudley or N. Y. C. R. R. (100-lb.), and the A., T. & S. F. (101-lb.—see above).

Notes on Recent Rail Design (Eng. News, July 25, 1907).—Illustrated section of 90-lb. rail; $5\frac{1}{2}$ " high, $5\frac{1}{2}$ " width of base.

Standard Turntable Pit; Seaboard Air Line Ry. (By Philip Aylett. Eng. News, Aug. 15, 1907).—For 70-ft. turntable. Illustrated details.

Single-Phase Electric Traction on the Rochester Division of the N. Y. C. R. R. (By W. N. Smith. Eng. News, Oct. 17, 1907).—Illustrated.

A Tracklaying Machine With Rail Carriers (Eng. News, Nov. 28, 1907).—Illustrated. Performance: Rails 33 ft. long, 2 to 2½ miles of track laid per day with 1 foreman, 4 men to operate the machine and feed ties and rails, 6 men to distribute and space ties, 8 spikers, 4 nippers, and 1 tie peddler.

New Interlocking Plant, Hoboken Terminal Yard, D., L. & W. Ry. (Eng. News, Jan. 30, 1908).—Illustrated.

General Formulas for Simple Curves (By J. C. Locke. Eng. News, Jan. 26, 1908).—Diagram and numerous formulas, prepared and used on highway track work.

Train Resistance (Eng. News, Mar. 26, 1908).

New Steel Rail Specifications of P. R. R. (Eng. News, April 16, 1908).

New Rail Sections and Specifications of the Am. Ry. Assn. (Eng. News, May 14, 1908).—Two types illustrated: A and B, each rolled at 60-, 80-, 90-, and 100-lb. Tables of properties.

Standards of Track Construction on American Railways (Eng. News, May 4, 1908).—Four large tables comprising tabulated data from 59 railroads: Table 1.—Standard Practice as Applied to Rails and Rail Joints: weight per yard; length; type of section; lightest in main track; joints; type; square or broken; number of bolts; size of bolts; spacing of bolts; nutlock; nuts. Splice bars; length; weight per pair. Special patented joints used). Table 2.—Standard Practice as to Ties and Plates: material; wood, and where obtained; average life in main track; cost; recommended for wear or decay mainly; size, length, thickness, width; number of ties per 33-ft. rail; spacing at joints; preservative process; number of treated ties in use. Tie-plates; make; size; weight; where used). Table 3.—Standard Practice as to Frogs and Switches (Frogs; standard pattern; type; rigid or flexible; numbers, for main track; numbers, for yards; flangeway between main rail, ins. Switches; standard pattern; length of switch rail. Miscellaneous). Table 4.—Standard Practice as to Spikes, Ballast and Protection (Spikes; style; size; screw spikes used. Ballast; kind

used; size of stone; depth under tie. Guard rails for curves; on what curves; flangeway, ins.; are tie rods or bars used to hold gage on sharp curves?)

Readjustment of Curves and Tangents in Maintenance-of-Way Work (By W. H. Wilms. Eng. News, Sept. 17, 1908).—Illustrated.

Some Special Designs of Rails and Tie-Plates (Eng. News, Oct. 15, 1908).—Illustrated sections of 85-lb. rails for Western Pac. Ry. ($5\frac{1}{2}'' \times 5\frac{1}{2}''$) and Great Nor. Ry. ($5'' \times 5''$); also plans of four types of metal tie-plates in use on different railways.

Cast Manganese-Steel Rails on Curves, Boston Elev. Ry. (By H. M. Steward. Eng. News, Oct. 22, 1908).—Table showing comparative life of rails of ordinary Bessemer, high carbon Bessemer, nickel-steel, manganese-steel and open-hearth.

A Study of Rail Pressures and Stresses in Track Produced by Different Types of Locomotives on Curves (By E. B. Stetson. Bulletin No. 104, Oct., 1908, Am. Ry. Assn.; Eng. News, Nov. 26, 1908).—Extensive table; and analytic discussion of pressures and stresses.

A Wedge Rail Fastening for Steel Ties (Eng. News, Dec. 24, 1908).—Illustrated. It requires no bolts or clamps; the width of gage can be varied as required by wear; neatness of gage can be obtained, even if the rail section is not exact; gives greater resistance to shearing, as compared with bolts; the fastening can be insulated; and it is impossible for derailed wheels to destroy the fastening.

New Rail Specifications for the P. R. R. (Eng. News, Jan. 14, 1909).

A 1200-Volt Direct-Current Electric Railway (Eng. News, Jan. 21, 1909).—The Pittsburg, Harmony, Butler & New Castle Ry. Table of horse powers.

The Disadvantages of Concrete Foundations for Railway Crossings (By R. P. Black. Eng. News, April 29, 1909).—(1) The concrete gives too rigid a bearing under frogs, causing an anvil blow at frogs which soon wears down the points, especially at flat crossings, on account of the greater distance between points. (2) This anvil or solid blow is hard on bolts, especially when high speed is maintained over frogs. (3) In a high speed track concrete cracks away from timbers on account of the excessive jar. (4) It is hard to maintain a good surface on the track, as the concrete footing does not permit of raising. (5) The rigid bearing is hard on equipment. (6) The concrete foundation for crossing is a failure. The only case where it can be used to good advantage is where traffic is light, speed low and angle of crossing 90° more or less.

Earthwork Calculations for Side Hill Work (By R. S. Beard. Eng. News, June 10, 1909).—Diagrams, formulas and tables.

A Railway Transfer Table Without a Pit (By H. V. Miller. Eng. News, July 15, 1909).—Illustrated.

Standard Specifications for Structural Steel for Buildings (Proc. A. S. T. M., Vol. IX., 1909).—Adopted Aug. 16, 1909.

Standard Specifications for Bessemer and for Open-Hearth Steel Rails (Proc. A. S. T. M., Vol. IX., 1909).—Adopted by Aug. 16, 1909.

Taper Curves Used on Southern Pacific R. R. (Oct. 28, 1909).—Tables, formulas and illustrations.

Special Type of Track Construction for Tunnels and Subways (Eng. News, Aug. 19, 1909).—Illustrated, with tables of cost.

Tie-Plates and Braces for Guard Rails on Sharp Curves; Natal Gov't Ry. (Eng. News, Nov. 11, 1909).—Illustrated description.

Street Railway Track Construction and Paving (Report of Comm. on Way, Am. St. and Interurban Ry. Eng'g Assn., Oct. 4 to 8, 1909; Eng. News, Nov. 11, 1909).—Use of T-Rails in Paved Streets:—Recommendations: (1) For track construction where type of pavement will permit, as macadam or other shallow pavement, the T-rail weighing not less than 8

lbs. per yd. adopted as "recommended practice" by the Am. Ry. Eng. and M. of W. Assn., 1908. (2) For heavy service in connection with deep block pavements, a T-rail 7 ins. high with a 6-in. base, 17/32-in. web and a head of 2½ ins. wide and 1-11/16 ins. deep, weighing about 100 lbs. per yd., as illustrated (not reproduced here). (3) For light service, in connection with deep block pavement, a T-rail 7 ins. high, 6-in. base, 7/16-in. web, 2½ by 1-9/32 in. head, and weighing 80 lbs. per yd., as illustrated (not reproduced here). (4) For heavy service in connection with deep block pavement on streets where traffic is confined to the railway strip, etc. (cities of large class), the half-grooved (or "Trilby") section recommended in 1907. **Other Subjects Discussed:**—Track in paved streets; Opinions of City Engineers, etc., as to St. Ry. track construction; Widening gages on curves; Cost and life of steel ties; Wear of gage lines of rails on tangents; Creosoted wood-block pavement; Spacing of ties; Setting of concrete foundation; Life of rail joints on paved streets; Efficiency of electrically brazed and soldered rail bonds; Discussions on rails, ties, foundations, paving.

Train Resistance by Various Formulas (Eng. Rec., June 4, 1910).—Table of train resistance in pounds per ton by various formulas: (1) Am. Ry. Eng. & M. W. Assn., Bulletin 114, p. 4; (2) Ditto, Bulletin 84, p. 100; (3) Am. Loco. Co., Bulletin 1001, p. 3; (4) Am. Ry. Eng. & M. W. Assn., Bulletin 120, p. 26. Experiments indicate that train resistance increases with the speed.

Elementary Theory of the Gyroscope in the Brennan Monorail Car (By E. V. Huntington. Eng. News, July 21, 1910).—Discussion of: (a) Steady precession; (b) Accelerated precession; (c) Application to the monorail car; (d) Efficiency of the Brennan apparatus; (e) Proportions of the car; (f) Proofs of theorems. Illustrated.

The Track and Line Construction of Electric Railways (Eng. News, Oct. 27, 1910).—Tabular results of inquiries as to general lines of practice on 18 interurban railways and 17 street railways in various parts of the country. The tables are: (I) Length, track arrangement and ballasting; (II) Grades and curves; (III) Rails and rail joints; (IV) Ties and tie-plates; (V) Frogs, switches and switch-stands; (VI) Pole equipment; (VII) Line and car equipment, signals, etc. These tables are accompanied by a general discussion of prevailing practices.

Mountain Rack Railways, and the Jungfrau Ry. in Switzerland (By E. Corthell. Eng. News, Oct. 27, 1910).—Includes a table of 57 railways in Europe, Asia and Australia, and North and South America, giving date of building, gage of track, length, grades of adhesion and rack, kind of action, minimum curve on rack, number and weight of locomotives, and axle weight.

Track Construction on the Chicago Street Railways (Eng. News, Nov. 1910).—"The complete reconstruction of the street railway tracks in Chicago was one of the requirements of the new system of municipal regulation and the agreement between the city and the companies, which went into effect about three years ago, and by which the city exercises a strong control over the construction, equipment, operation and financial affairs of the street railways." The supervision of this work is in the hands of a Board of Supervising Engineers, composed of Bion J. Arnold, George Weston, Harvey B. Fleming, John Z. Murphy and A. L. Drum. This article gives illustrated descriptions of:—(1) Types of track construction (grooved steel rails on steel ties embedded in concrete; same with wooden ties; moved girder rails on wooden ties on broken stone ballast; T-girder rails on brick paving; tram-head girder rails on wooden ties in macadam). (2) Track material (rails, with table; rail joints; ties; tie-plates; spikes and bars; switches and frogs). (3) Foundation and paving (broken stone; concrete; paving; track spacing; track grade and street grade; curves at street intersections). (4) Methods of construction. (5) Track deflection.

The Electric Bolt Lock as Applied to Interlocking (Report of Committee on Power Interlocking, presented at annual meeting of Railway Signal Association, Oct. 11-13, 1910; Eng. News, Nov. 3, 1910).—The principal merit is safety.

Gravity Freight Classification Yard for the P. R. R. at Northumberland, (By W. A. MacCart. Eng. News, Nov. 17, 1910).—Illustrated design.

60.—HIGHWAYS.

A.—TRACTION.

Power of a Horse.—It is generally estimated that an average horse weighing 1200 lbs. can exert a force of 100 lbs. for a day of 10 hours at the rate of $2\frac{1}{2}$ miles per hr., on a fairly level grade; and for a short haul he can exert a force of $2\frac{1}{2}$ times the above, or 250 lbs. A constant force of 100 lbs. at $2\frac{1}{2}$ miles (13200 ft.) per hr. is equal to just two-thirds of a horsepower (H. P.), and for 10 hrs. it is equal to $6\frac{2}{3}$ horsepower-hours, or 13 200 000 ft.-lbs. of work.

Effect of Road Surfaces on Traction.—The tractive force required to move one ton of 2000 lbs. on various kinds of level roads is approximately as follows:

	F	W	$F:W$	$= A$
Earth road.....	100 lbs. per ton	2000 lbs.	$= 1:20$	$= .05$
Macadam road.....	40 "	"	$= 1:50$	$= .02$
Granite blocks.....	30 "	"	$= 1:66\frac{2}{3}$	$= .015$
Brick pavement....	25 "	"	$= 1:80$	$= .0125$
Asphalt pavement..	20 "	"	$= 1:100$	$= .01$
From {	8 "	"	$= 1:250$	$= .004$
Steel rails.....	$7\frac{1}{2}$ "	"	$= 1:266\frac{2}{3}$	$= .00375$
To... {	7 "	"	$= 1:285\frac{1}{3}$	$= .0035$

Experiments in Iowa showed the following tractive resistances: Brick pavement, 25.4 to 58 lbs. per ton; asphalt pavement, 23.3 to 67.8 lbs. per ton. (See page 1142.)

Effect of Grades on Traction.—In the above case, if we let F = the tractive force, and W = the load, then will $\frac{F}{W} = A$, the tangent* of the angle of repose, or grade of the road at which the load would just begin to slide or descend of its own weight. Hence, if F lbs. are required to move a load W on a level, it is clearly evident that $2F$ lbs. would be required to haul it up a grade $G = A$, $3F$ lbs. up a grade $G = 2A$, etc., approximately. This proposition is often erroneously neglected, the usual formula given being, $F = WG$, which F = tractive force, W = load, and G = grade. The correct formulas are:

$$F = W (A + G) \text{ in ascending.....(1)}$$

$$F = W (A - G) \text{ in descending.....(2)}$$

Hence
$$W = \frac{F}{A + G} \text{ in ascending(3)}$$

Records of actual tests appear in various works stating that a horse which can pull 1000 lbs. on a level road, can pull only 900 lbs. up a 1% grade, 810 lbs. up a 2% grade, 750 lbs. up a $2\frac{1}{2}$ % grade, 720 lbs. up a $2\frac{3}{4}$ % grade, 640 lbs. up a $3\frac{1}{2}$ % grade, 540 lbs. up a 4% grade, 500 lbs. up a $4\frac{1}{2}$ % grade, 400 lbs. up a 5% grade, and 250 lbs. up a 10% grade.

Problem.—On an extremely bad earth road it requires a constant force of 100 lbs. to pull 1000 lbs. on a level. What would be the maximum allowable grade, assuming that F could be increased to 250 lbs. while ascending grade?

Solution.—Transposing equation (3), above, we have, since $A = 100 + 1000$, Maximum grade, $G = F + W - A$

$$\begin{aligned} &= \frac{250}{1000} - \frac{100}{1000} \\ &= 0.15 = 15\%. \text{ Ans.} \end{aligned}$$

* Approximately; see Sec. 59, Railroads, page 992.

B.—ROADS AND STREETS.

Definitions.—A Street is a public way in a city or town, and consists generally of a roadway and two sidewalks. A Road consists essentially of a roadway or public thoroughfare through a county district, and with or without sidewalks. City streets are usually paved, while roads, and roadways of streets in small towns, are merely surfaced. Roads and streets may be classed according to the kind of surface or pavement, the selection of which will depend upon the kind and amount of traffic, grades, cleanliness desired, material available, climate, allowable first cost, cost of maintenance, etc.

Dirt Roads, sometimes dignified by the name *Earth Roads*, are the pioneers in any new country. Dirt from the sides is simply thrown up into the center, forming a sort of crown for lateral shedding of rain water. In the Middle West, dirt roads are constructed very rapidly and cheaply by plowing one or two furrows on either side, and using scrapers in casting this material up for the crown of the road. Where extensive road-making is contemplated, it is well to figure on regular road-making machines.

Corduroy Roads are probably among the first in any new country, and in thinly populated sections generally, to supplant the common dirt road in low, marshy, wet ground. The typical corduroy road consists of round sticks of wood a few inches in diameter, laid transversely across the road. These are sometimes supplemented with half-round sticks, or slabs from saw-mills. At best they are but makeshifts, and give way sooner or later to plank- or other construction of surface of a smoother character and calling for less tractive power in hauling. Corduroy roads are often improved by crowning them with gravel, using sticks or poles as a foundation.

Plank Roads are usually the first form of improvement in timbered sections where there is much rainfall. On many of our old maps, in various sections of the country, we may see the "Old Plank Road" shown in dotted lines. The typical plank streets now being constructed in our small towns of the Pacific Northwest are composed of planking 3" to 4" thick, laid transversely, and spiked (or not) to longitudinal wooden stringers of size say 4" by 10", more or less, spaced about 4-ft. centers. The sidewalk planking is usually about 2" thick, laid with a slope of about $\frac{1}{4}$ " per ft. toward the curb. A simple gutter is shown in Fig. 1. For the roadway, the planking is sometimes laid level from gutter to gutter, and sometimes crowned in the form of a parabola, the quarter points being $\frac{1}{4}$ the height of the middle. The method sometimes adopted of laying the middle third of the roadway level, and the sides sloping, is particularly objectionable because of the two continuous longitudinal joints formed along the edges of the level portion. If the street is on a steep grade, it is generally best to have the longitudinal stringers under the planking "broken" and not "continuous," in order to prevent excessive wash of the soil. Two nails are used at each intersection of plank with stringer. Barbed wire nails are most commonly preferred. Sometimes the planks, if very heavy, are simply laid on the stringers without spiking, but this method is objectionable. The stringers should be imbedded firmly in the ground.

Fig. 1.

Gravel Roads are excellent when properly made. Angular, pit gravel is the best; smooth, sea-polished gravel will never bind properly unless a binder is added, and that increases the expense. After the gravel has been screened, $\frac{1}{4}$ " to $1\frac{1}{4}$ ", it is spread on the ground in 3" or 4" layers and thoroughly compacted, after sprinkling, with a steam road roller weighing from 3 to 10 tons. A small quantity of clay added to the gravel acts as a binder and it is still further improved if mixed with crushed gravel or small broken limestone. Sand should not be used.

Gravel Walks are constructed practically in the same manner. The main thing to look out for in gravel construction is good drainage, as the clay binder is easily softened when saturated. Tile or box under-drains should be laid to carry off the surplus water, and their proper use greatly decreases the cost of repairs. Coal tar is sometimes used with gravel in making foot-walks, but the result is usually unsatisfactory.

Broken-Stone Pavement has undergone rapid improvement since the advent of the rock crusher and the steam road-roller. The original Telford and Macadam methods, about 1825, have been supplanted by more modern methods of construction. In providing for a good pavement, under-drainage should be provided when required; a sub-grade should be prepared by removing all perishable matter and the top soil; the under-soil should be compacted and a foundation of gravel prepared when necessary, if the best results are expected. The broken-stone should not be larger than 2" for the softer rock or 1½" for the harder, and if clean it should not (generally) be screened, as the stone dust and chips make good binders. A soft stone foundation and a hard stone surface are the best. Sand and gravel may be employed to fill the voids, but very little if any clay or loam should be used. Crushed granite should never be used. Trap or basalt is best for the surface, and limestone for the bottom. The material is spread in layers of about 4" to 4½", sprinkled sufficiently, and compacted with steam road rollers weighing 5 to 10 tons. It will roll to about ¾ the spread thickness. The thickness of broken stone pavement is usually from 6" to 10", although 1" is quite common. It is to be noted that a thin pavement laid on a good gravel foundation is often superior to a much thicker pavement laid directly on the soil. The rolling should begin at the sides and work toward the crown of the road.

Hydraulic-Cement Pavement consists of a 3" to 6" concrete base underlying a wearing surface composed of one part hydraulic cement to two parts finely crushed rock, 1½" or more in thickness. The concrete base may rest on a gravel or cinder bed. The finished surface may be flushed with a 1 to 1 sand and cement mixture.

Cement Sidewalks usually consist of a 1" to 1½" wearing surface composed of a 1 to 1 sand and cement mixture, overlaying a 3" to 4" concrete base resting on cinders. The wearing surface is often flushed with a pure, nearly pure, cement mortar.

Wood-Block Pavements have given good results when properly constructed, but the expense of preparing good foundations necessary to keep blocks in even surface is considerable. The best foundation is a layer of concrete, say 4" or more in thickness, and this is the practice in Europe where this kind of pavement has reached its highest perfection. It is also coming standard in many of the principal cities of the United States. Experiments have been made in New York City and elsewhere in this country with varying degrees of success, but it can be stated that, generally, the trend is toward some more permanent form of construction. This is the case also in many of our western cities, even those of the Northwest where timber is very plentiful but where the wood block is being supplanted by salt, brick and Belgian block pavements. In section, the blocks may be various shapes, round, square, rectangular, etc., but the rectangular is perhaps the most common. The blocks should be laid with the ends or grain vertical and with close joints. In the cheaper construction, some parts of the West, they are laid on a bed of sand resting on a gravel foundation, or on planking of single or double thickness, and with joints bed with sand. In the better construction, they are laid on a bed of tar spread on a concrete foundation, with joints smeared with tar, salt or cement, and expansion joints provided at intervals and along curb. Many engineers prefer to lay the blocks so the course of joints be diagonal to direction of traffic. If laid square they are more easily injured by the corks of the horses' shoes. A common objection to wooden block pavement is made on the ground of cleanliness or sanitation. The blocks should be treated with some preservative, as creosote, but this is not always done. Blocks so treated expand much less after being laid, and provision need be made therefor; but if laid untreated they will swell from the absorption of moisture, and careful provision must be made for expansion, at frequent intervals. The writer has seen "blisters" raised on surface because of lack of provision in this respect. The harder woods, such as oak, are not generally used in this country, as they wear too slippery.

Cobblestone Pavement consists of cobblestones from 4" to 6" in longest dimension, set vertically, with the fattest end up, in a bed of gravel, thoroughly bedded, and with joints filled with gravel. This pavement is but a makeshift for roadways, and is being supplanted by Belgian blocks or other pavement of better quality. It is frequently used for gutters.

Belgian Block Pavement consists of hard trap or basalt blocks of stone laid in parallel courses and rammed into a bed of sand, with sand joints. The blocks are usually about 7 ins. high and 5 or 6 ins. square.

Granite Block Pavement is supplanting the Belgian blocks as the latter did the cobblestones, and it is now considered the best pavement for heavy traffic. The blocks may be, say 7" deep, 3" wide and 10" long, laid with continuous parallel joints or courses at right angle to the direction of traffic, on a concrete foundation not less than 4" thick; 6" to 8" is better for unusually heavy traffic. They are laid directly on a thin layer of sand, well rammed to a firm bed, and the joints filled with bituminous cement.

Brick Pavement has become quite popular in recent years in certain sections of the country where a moderately durable pavement is required for all-around traffic at not too great expense. The brick should be uniformly hard-burned and tough, and subjected to rigid inspection before being laid. They should be laid on edge in parallel courses (with broken joints) at right angle with the direction of traffic, on Portland cement concrete 4" or more in thickness, with a cushion layer of sand, and with small joints so the sand will work up into the joints during rolling. The bricks may be of the ordinary size, or vitrified blocks may be used. At street intersections, the courses may be diagonal with either street. There is no advantage in laying bricks herring-bone fashion as in Fig. 2, except perhaps to please the eye, as in sidewalk fancies. Straight, transverse courses give a better foothold for the horses. Bituminous cement, or, better, Portland cement grout should be used in filling the joints after the bricks are laid. Sand is far inferior and should never be used.

Fig. 2.

Asphalt Pavement takes first rank for combined general serviceability, low tractive resistance, cleanliness and hygienic properties. It consists, in general, of about a 4" base of hydraulic cement concrete or bituminous concrete, for a foundation. On this base is laid a $\frac{1}{2}$ " (finished) cushion coat or binder which contains about 3% more asphalt cement than the surface coat. The surface or wearing coat is laid with a finished thickness of about 2". It is composed of asphaltic cement (85 parts pure asphalt and 15 parts heavy petroleum oil) 15%, sand and stone dust 80%, and crushed carbonate of lime 5%, more or less; the proportions often being varied. A bituminous base is composed of broken stone coated or mixed with coal-tar cement. It usually calls for a slightly thicker cushion coat than the above, say 1" to 1 $\frac{1}{2}$ ", and also a 1 $\frac{1}{2}$ " wearing coat.

Asphalt Paving Blocks are made in a variety of shapes, and laid on sand, gravel, or concrete foundation.

Bituminous-Rock Pavement is made from bituminous sandstone or limestone, of which extensive quarries are worked in California, Kentucky, and elsewhere. The quarried rock is broken up, melted, and rolled while hot. A proper amount of asphalt is added if necessary to give the required proportions. The product is commonly called rock asphalt. This is heated to about 200° F. and spread in a finished layer, after rolling, of about 2 $\frac{1}{2}$ " in thickness.

C.—PAVEMENT SPECIFICATIONS.

ALLEGHENY COUNTY (PA.) ROAD SPECIFICATIONS.

(Geo. T. Barnsley, Chf. Rd. Engr.)

Work by Contractor.—Do clearing, grubbing, leveling, grading, surfacing; make excavations, embankments, ditches, drains, gutters; construct masonry, stonework; build fences and protection railings required. In fact, complete road and structures. **Excavation.**—Straight classification, and includes trees and clearing. Embankments rolled in layers not over 12" thick. Earthwork measured and paid for by cu. yd. in excav. When required, top soil to be removed from road surface and deposited as directed. May require clay and spongy material to be removed to any depth and replaced with gravel or coarse stone. Where possible, embankment slopes to be covered with 3" of surface loam. No work on covered drains, paved gutters or foundations to be paid for in excavation. Ordinarily, no allowance for excavation beyond lines of cross-section. **Clearing.**—Trees, stumps, bushes, roots, etc., to be removed; and no perishable matter allowed under embankments. **Drainage.**—Where required, a trench 12" wide at bottom and 15" wide at top to be excavated at least 30" below sub-grade; at least 3" of gravel to be placed in the bottom, and on this lay salt-glazed vitrified drain-pipe as directed, with bell and spigot joints, laid with open joints, ordinarily; then fill to 6" above pipe with gravel between 1" and 1½" screening; then fill to top of trench with stone between 3" and 2" screening. Open ditches paid for as excavation; covered drains, by the lin. ft., price to include all expenses of trenching, furnishing and laying pipe, refilling, etc. **Rubble.**—For small culverts, ordinarily, and for retaining walls. Spalls used only where needed for leveling or pinning; large stones for foundation courses, and for heads and faces of culverts. Covering-stones of culverts to be not less than 12" thick, laid close together, and cracks closed with pinners. All walls to be of coursed rubble, laid with best bed down; breaking joints at least 1 ft., and to have no pinners on the face; joints not over ½". End walls of culverts, and all retaining walls, to be capped with roughly-dressed coping stones 16" thick, at least 24" wide, and as long as possible. **Masonry** paid for by cu. yd., actual measurement. **Fencing.**—Posts to be straight locust, not less than 6" dia., with knots hewn down to face; spaced 8 ft. apart and set 3 ft. in ground, with 3½ ft. above surface. Top 14" sq. and notched into top of post so all surfaces will incline 45°; in addition to spiking, it shall be held with a ½" by 1½" iron strap 30" long, securely nailed. Side rail, 2" by 6", notched into inside of posts and spiked. Paid for by lin. ft. in place. **Shaping Sub-grades.**—Before the foundation is laid, the roadbed shall be shaped and rolled with a steam roller of at least 10 tons, all resulting depressions filled, and the surface again rolled. **Foundations.**—Upon the sub-grade so prepared, a foundation to be laid according to method a, b, or c: (a) For clay or wet soil, a Telford foundation, with stones 6" to 8" deep, not over 4" wide on top, and 6" to 16" long; laid by hand with the broadest edges down and longest side across the road, on the sub-grade. Not over 10% to be less than 7" deep. Stones to be broken at joints; projecting points to be broken off with hammer; wedging stones to be driven until foundation is to grade and 8" thick. Foundation to be rolled with not less than 10-ton roller. (b) For soil of medium strength, spread evenly to finished depth of 8" broken stone between 3½" and 2½" ring dia.; roll this with roller of not less than 10 tons until the mass is firmly imbedded into the earth sub-way and the top is 4" above finished grade. (c) Where nature of soil will permit, spread broken stone to 6" finished depth, and roll as in b. **Surfacing.**—Upon the foundation prepared according to a, b or c, spread two layers of broken, close-grained, hard rock, granite, lignite or limestone, free from dirt or dust, and broken into uniform or regular cubes, and comparatively free from flakes or scales; crushing strength of not less than 20000 lbs. per sq. in. Contractor required to furnish certified copies of railroad weights for macadam material shipped and placed, or cu. yds. of same when furnished by local quarry. The first layer to consist of 2" to 2½" broken stone and to be 2" when consolidated; rolled with at least a 10-ton roller, all depressions filled with stone of same quality, and again rolled to finished surface 2" above finished grade. The second layer to consist of 2" in consolidated thickness of ¾" to 1½" broken stone to which may be added a proportionate amount of ¾" to ¾" screenings, free from dust; the whole surface then to be

rolled to finished grade. If ordered, dust from the crusher shall be laid on as a binding course, just sufficient to bond the top and make the surface smooth, and in no case thicker than $\frac{1}{2}$ "; then sprinkled and the whole rolled until mud flushes to the surface, and until roller causes no wave in surface. Engineer may vary macadam surfacing from 6" for heavy traffic, to 4" for light traffic; and increase width of macadam from 14 ft. to 22 ft., or decrease it to 10 ft. **Mile Stones.**—Cut granite, 10" sq. at top and 12" sq. at bottom; 5½ ft. long, 3 ft. above ground.

BOSTON (MASS.) PAVEMENT SPECIFICATIONS.

(William Jackson, City Engineer.)

GRANITE BLOCK PAVEMENT—BRICK SIDEWALK.

Covers, etc.—City to reset and repair catch-basin and manhole covers and other structures to be left in street. **Preparing Site.**—Ground to be brought to proper sub-grades; bottom of excavation for sidewalks and edgestones to be rammed and rolled, and bottom for roadway to be watered thoroughly, made solid and of even surface, with heavy steam road roller, places not accessible to be tamped with hand rammers; unsuitable bottoms to be excavated and refilled. **Edgestones.**—(a) New edgestones, including circulars and corners, to be of Quincy, Cape Ann, or other equally good granite, all of same color, cut in lengths not less than 6 ft., free from bunches and depressions, and have horizontal beds; ends to entire depth to be square with top, and set with mortar joints not over $\frac{1}{4}$ "; to be out of wind; hammered surfaces to be full to line; to be 7" wide on top and 20" deep; to be hammered on top, fine pointed 3" down on the back, squared with the top, and fine pointed 10" down on the face; remainder of face to be straight split; face to be cut square with top. (b) Excavation to be 18" wide, and its bottom to be at the sub-grade of 24" below top of finished edgestone. (c) Upon this bottom, the foundation to consist of clean coarse gravel 4" thick when rammed; then more gravel to be spread, the edgestone laid thereon, with closed joints, spaces under stone thoroughly filled with gravel and tamped firmly to grade. (d) Excavation on each side of edgestone then filled to the sub-grade of roadway and sidewalk, respectively, with clean gravel, laid in 4" layers, each rammed and tamped under and around the edgestone, and joints carefully pointed, top, front and back, with mortar, of equal parts Natural hydraulic cement and clean, sharp sand. (e) Good clean gravel then to be laid, without ramming, against and up to top of edgestone on sidewalk side; after which the roadway paving is to be laid and rammed, care being taken not to disturb the grade of stone; and thereafter all gravel and other material on the sidewalk side to be excavated to depth of 12" below top of edgestone, and replaced by gravel in 4" layers, rammed, to sub-grade of sidewalk. **Roadway.**—(Either gravel base or concrete base.) **Gravel Base.**—Sub-grade to be 12" below finished surface of roadway; and on this lay gravel base, consisting of coarse-screened paving gravel, not larger than $\frac{1}{2}$ ", thoroughly rammed into a solid layer, 4" thick when completed. **Concrete Base.**—Sub-grade to be 16" below finished surface of roadway; and on this lay concrete base, consisting of 1 part Portland cement, 3 parts screened coarse sharp sand, and 7 parts broken stone, not larger than 2½" and very few smaller than $\frac{1}{2}$ ", and evenly graded between these sizes. (b) Templates and other forms used to hold concrete in place, to be set true to lines and grades, and secured firmly. (c) Cement and sand, just before concrete is to be used, to be mixed dry, then add only enough water to make a paste, thoroughly worked with hoes or other tools; broken stone is then wet, after which the materials are handled rapidly to the end; paste is spread evenly over pile of stones, on platform, and the whole turned over at least twice, thoroughly mixed, put in place at once, and thoroughly rammed so that interstices between stones are filled with mortar and water flushes to surface, made true and parallel with finished roadway. (d) After ramming, concrete allowed to set; defects remedied with good concrete. (e) When Portland cement is specified it is to be Dyckerhoff, Star Stettin, Alsen, Alpha, Lehigh, Vulcanite or Atlas; when Natural cement is specified it is to be Natural hydraulic cement, equal to best Rosendale; other brands can only be substituted when approved. No cement will be tested in cars, or in course of transportation, or on the street. **Granite Block Paving.**—(a) Standard granite blocks, 3½" to 4" wide, 7½" to 8" deep, and 9" to 14" long (average not less than 11½"); edges to be sharp and straight, right angle both horizontally and vertically, faces to be straight-split, free from bunches

and depressions exceeding $\frac{1}{2}$ ", and carefully piled. (b) Upon the gravel or concrete base, spread a layer of clean, coarse-screened bedding sand, on which lay the blocks in courses of uniform depth, at right angle with street line (ordinarily), with close joints, the longitudinal joints broken by lap of at least 2", sufficient sand being used to bring blocks to grade, after thorough ramming; then covered, and covering raked and swept until joints are filled, blocks then thoroughly rammed to unyielding bed, with surface parallel with grade and crown required; then again covered and raked and swept as before; blocks again rammed until solid and secure at grade and crown of finished roadway; no ramming done within 15 ft. of paving being laid; one rammer to each paver. (c) If blocks are laid with Gravel Joints, cover blocks (after being rammed) with clean, coarse-screened sand, dried by artificial heat if necessary, and rake and sweep until joints are filled; entire area covered with 1" layer. (d) If blocks are laid with Pitch Joints, lay as above, but the covering is to be washed pebbles, equal to best Long Island white pebbles, $\frac{1}{2}$ " to $\frac{3}{4}$ ", thoroughly heated and raked or swept, filling joints to within 1" of surface; joints then filled with paving cement of proper consistency, flush to grade and crown of finished roadway; the cement left upon top of blocks to be covered with dry sand, sufficient to absorb the cement if required. The paving cement to be obtained by the direct distillation of coal tar, and kept at a temperature of 300° F. while being used. **Flagging Crosswalks.**—(a) Granite flagging stone, each exactly 2 ft. wide, not less than 4 ft. long, of same thickness as the others, not less than 6" nor more than 7", of best grade and quality, uniform color, top rough pointed, and ends jointed and square-cut to full depth of stone. (b) Upon the gravel or concrete base, spread a layer of clean, coarse-screened bedding sand, in which lay the flagging crosswalks; to be rammed and tamped to a solid and unyielding bed, sufficient sand being used to bring surface of flagging to grade and crown of finished roadway, after ramming. (c) If crosswalks are to be laid with Gravel Joints, fill joints with sand as for block paving with gravel joints. (d) If crosswalks are to be laid with Pitch Joints, fill joints with paving cement as for block paving with pitch joints. **Brick Sidewalks.**—(a) Bricks to be burned hard entirely through, straight-edged, of compact texture, regular and uniform in shape and size; bricks which after being thoroughly dried and then immersed in water for 24 hrs. absorb more than 16% of their volume, may be rejected; any edge of a brick sidewalk not against a curb or buildings is to be supported by a continuous spruce plank, 2" by 8", held by 2" by 4" spruce stakes driven in the round. (b) Excavation for sidewalk is to have its bottom brought to sub-grade 8" below finished surface of walk, and on this lay foundation consisting of coarse-screened paving gravel, not larger than $\frac{1}{2}$ ", rolled and rammed so as to be 4" thick when completed. (c) On this foundation, spread a layer of at least 2" thick of clean, sharp sand, parallel with finished grade of walk; on this, the bricks are to be laid on their widest side, in courses of uniform width and depth, at right angle with street, or in herring-bone fashion, with close joints, all longitudinal joints broken by at least 2"; the bricks then to be covered with clean, fine, dry sand, using screen of 20 meshes to an inch; and upon the bricks, a plank, covering several courses, is to be placed and rammed carefully with a heavy hammer to a firm bed, with surface to proper grade; then spread fine sand over surface and sweep or rake so as to fill joints.

WOOD BLOCK PAVEMENT—BRICK SIDEWALK.

Covers, etc.—(Same as for granite block pavement.) **Preparing Site.**—(Same as for granite block pavement.) **Edgestones.**—(Same as for granite block pavement.) **Roadway.**—(Either gravel base or concrete base.) **Gravel Base.**—(Same as for granite block pavement.) **Concrete Base.**—(Same as for granite block pavement, except that sub-grade is to be 10½" below finished face of roadway for wood block pavement.) **Flagging Crosswalks.**—(Same as for granite block pavement.) **Wood Block Pavement.**—(a) Southern long-leaf yellow pine, not less than 90% of heart, texture permitting satisfactory treatment; sticks inspected at works before being sawed into blocks. Blocks to be of sound timber, free from bark, loose or rotten knots, or other defects which would be detrimental to life of block or interfere with setting; no second growth timber allowed. (c) Blocks to be well made, angular and of uniform size; depth (parallel to fiber) 4"; length not less than 8"; width not less than 4"; depth and width to be exact. (d) The Method of Treatment to conform to the best and most advanced knowledge of the art, the purpose being to allow contractors to manufacture block by

following any preferred detail and by use of any process which may properly be adapted to secure the results demanded, namely, that all parts of each block shall be thoroughly impregnated with the preservative (an antiseptic and water-proofing oil), not less than 20 lbs. per cu. ft. of wood; the block not to split or warp, and to have a specific gravity greater than that of water. (e) The preservative to have a specific gravity not less than 1.12 at 68° F. When distilled in a retort, with the thermometer suspended not less than 1" above the oil, it is to lose not more than 35% up to 315° C. and not more than 50% up to 370° C. Oil to be free from adulteration or foreign material. (f) After treatment the blocks are to show such waterproof qualities that, after being dried in an oven at a temperature of 100° for a period of 24 hours, weighed, and then immersed in clear water for a period of 24 hours and weighed, the gain in weight is not to be greater than 3%. (g) Material and blocks may be rejected if not satisfactory. (h) Upon the surface of the concrete foundation is to be spread a bed of cement mortar $\frac{1}{2}$ " thick, the surface to be composed of slow-setting Portland cement and clean, sharp sand, free from pebbles over $\frac{1}{4}$ " diameter, 1 part cement to 4 parts sand; this mortar top to be thoroughly rammed into place with concrete rammers until all unevenness in the concrete is taken up, and is then to be "struck" to a true surface parallel to top of finished pavement. (i) On this mortar surface, lay the blocks with the grain vertical and at such an angle with the curb as may be directed; to be laid in parallel courses with tight joints, firmly imbedded in the mortar bed so as to form a true and even surface. (j) Joints then to be filled with cement grout, 2 parts clean sand and 1 part Portland cement, mixed to a liquid form, and the surface of the block slushed with same and the joints swept until completely filled; expansion joints, filled with a paving cement of proper consistency, to be made next the edgestones. Surface then covered with $\frac{1}{2}$ " of screened sand. (k) Where grade of street is more than 8%, the blocks are to be not less than 8" nor more than 10" long, and the upper edge of each block is to be cut away for a width of $\frac{1}{4}$ ", and a depth of 1", to provide a transverse groove between each course of blocks when laid in place; or such other construction is to be used as will provide an equally good foothold for horses. **Brick Sidewalks.**—(Same as granite block pavement.)

ASPHALT PAVEMENT.

Bituminous Concrete Binder.—(a) On the concrete base, covered with Trinidad asphalt, lay the binder. (b) In making, use 15 gallons Trinidad asphaltic cement and 1 cu. yd. of crushed stone, not over $\frac{1}{2}$ ", heated and thoroughly mixed. (c) In using, this binder, while hot and plastic, is to be evenly spread and thoroughly rolled until the roller ceases to make any impression, the compressed binder to be at least $\frac{1}{4}$ " thick, on which an asphalt wearing surface is to be laid. **Trinidad Wearing Surface.**—For Trinidad asphalt pavement, the wearing surface is to be composed of (1) Trinidad Lake asphalt, specially refined and brought to a uniform standard of purity and gravity; (2) heavy petroleum oil, freed from all impurities and brought to a specific gravity of 18° to 22° Baumé, and a fire test of 250° F.; (3) sand entirely free from clay or other objectionable material, of such size that none of it will pass through a No. 80 screen, and all through a No. 10 screen; (4) powdered carbonate of lime of such degree of fineness that 15% by weight will pass through a No. 100 screen, and all through a No. 26 screen. (b) In making, 100 parts of the asphalt and 15 to 20 parts of the petroleum oil are to be made into an asphaltic cement, which is to have fire test of 250° F., and a temperature of 60° F. is to have a specific gravity of 1.19; this cement and the sand are to be kept heated separately to about 300° F., and the carbonate of lime is to be kept cold; 70 to 83% of the sand so heated and 5 to 15% of the lime while cold are to be thoroughly mixed together, but the lime may be reduced or omitted if the sand is satisfactory in quality and quantity; to this mixture, while so heated, is to be added 12 to 15% of asphaltic cement at a temperature of about 300° F., kept at that temperature, and thoroughly mixed in a suitable apparatus. (c) In using, spread the above mixture, at about 250° F., evenly on the concrete binder by hot iron rakes, to produce a uniform surface; then compress with tamping irons and hand rollers and sweep a small amount of dry hydraulic cement over it; then thoroughly compact by steam roller, not less than 5 tons, until roller fails to make any impression on surface, the finished wearing surface not to be less than $\frac{1}{4}$ " thick. **Sicilian Wearing Surface.**—(a) For Sicilian asphalt pavement, the wearing surface is

to be composed of (1) natural bituminous limestone rock, mined by the "United Limmer & Verwohle Rock Asphalt Co., Limited," at Ragusa, Sicily; (2) limestone rock mixed by said company at Vorwohle, Germany. (b) In making, 3 or 4 parts of the Ragusa rock are to be thoroughly mixed with 1 part of the Verwohle rock, and this mixture to be crushed, pulverized to a powder and passed through a fine sieve, nothing being added or taken from the powder. (c) In using, spread the above mixture, at about 160° F., evenly upon the concrete base, and compress evenly by heated hand rollers and rammers, smooth by heated smoothers and roll for 2 or 3 days with a heavy iron roller until it ceases to make any impression, the finished wearing surface not to be less than 2" thick. **Coal Tar Painting.**—The wearing surface, to a width of 24" from curb, is to be painted with coal tar distillate and ironed with hot smoothing irons, to make a continuous layer without holes.

BITULITHIC PAVEMENT.

Sub-Grade.—6" below finished surface of roadway. **Crushed Stone Foundation.**—Upon the sub-grade, lay a foundation consisting of a layer of hard crushed stones to a depth of 6", and compress with heavy steam road-roller. Upon these stones, spread a thin layer of Warren's No. 1 Puritan brand bituminous semi-liquid cement, to be flexible and to unite freely with the cold stones. Upon this cement, spread a heavy coating consisting of 1 gallon of Warren's No. 24 Puritan brand hard bituminous cement to each sq. yd. of surface, the wearing surface immediately spread thereon, and the stones firmly bound together and with the wearing surface by this coating. **Wearing surface.**—Hard crushed trap rock to be heated in a rotary mechanical dryer to a temperature of about 250° F. This material then to be elevated, passed through a rotary screen having 6 sections, each with a different sized opening, the largest 1½" and the smallest ½" diameter, the materials to be separated by these sections into 6 lots, each lot consisting of the materials passing through one of the sections of the screen into a separate compartment or bin. The materials in each lot are then weighed separately and mixed with the materials of each of the other lots into batches, in the proportions which shall have been determined by laboratory tests to give the best results, that is, the most dense mixture of mineral aggregate having inherent stability; and if the fine crushed rock does not provide the best proportion of fine-grained particles there must be supplied not more than 15% of hydraulic cement, pulverized stone or very fine sand. Each batch is then passed into a "Twin Pug" or other approved form of mixer, and then mixed with a sufficient quantity of Warren's No. 21 Puritan brand bituminous water-proof cement to thoroughly coat all the materials and fill all voids; the cement when used is to be at a heat between 200° and 250° F., and the amount used with each batch is to be accurately weighed and used in such proportions as shall have been determined by laboratory tests to give the best results, the mixing to continue until mixture is a uniform bituminous concrete, that will when cold have as closely as practicable the solidity and density of solid stone. This concrete is immediately after mixing to be hauled to the street, spread on the No. 24 cement, and compressed with a steam road-roller to finished thickness of 2". **Surface Finish.**—On the wearing surface, a thin coating of Warren's quick-drying bituminous flush-coat composition is to be so spread over the surface that any unevenness or honeycombing in the concrete is filled. A thin layer of stone chips is then to be led into the surface so it will be gritty and not slippery. **In General.**—Each layer of the work to be kept as free as possible from dirt so that the layers will unite. Bituminous cement used shall be free from water, petroleum oil, water gas or process tars, and all light oil, naphthalin and other stalline matter susceptible to atmospheric influences removed by refining.

MACADAM ROADWAY—CRUSHED-STONE SIDEWALK.

Granite Block Paving.—To be used for gutters and brows for crosswalks; blocks to be 3½" to 4½" wide, 7" to 8" deep, and 7" to 12" long (average not less than 10"). Sub-grade 12" below finished surface; on this, the gravel base thick when completed. On this foundation, spread a layer of bedding 1", and in this lay the blocks, in courses of uniform width and depth at right angle with street line (ordinarily), with close joints, longitudinal joints being at least 2", enough sand used to bring blocks to grade; usual spreading of gravel on surface, sweeping and ramming. **Brick Block Paving.**—To be used for gutters and crosswalks; blocks to be re-pressed, hard, tough, com-

pletely vitrified, rectangular in shape, uniform in size and color, homogeneous in texture, and substantially 3" wide, 4" deep, 9" long. Rattler Test for abrasion to be as specified by Natl. Brick Manfrs'. Ass'n*; average loss in weight not to exceed 20%, and no one brick to lose more than 24%. Absorption Test, using 5 bricks previously subjected to rattler test, or bricks broken in half; bricks to be dried 48 hrs. at 230° to 250° F., then weighed and immersed in water 48 hrs., wiped and weighed, increase in weight not to exceed 4%. Sub-grade for brick blocks to be 10" below finished surface; on this, lay 4" layer of paving gravel. On this foundation, spread a layer of bedding sand, and in this lay the bricks, in courses of uniform width and depth at right angle with street line (ordinarily), with close joints, longitudinal joints lapping at least 2", enough sand used to bring blocks to grade, usual spreading of gravel on surface, sweeping and ramming. **Macadam Surface.**—Sub-grade 6" below finished surface; on this lay the macadam surface, made as follows: Hard, durable, broken stones, either of the best quality of broken trap or Roxbury conglomerate, or of acceptable field stone, 2½" to 1" diameter screen, free from round or other ill-shaped or improper stones, to be spread over whole surface of base, and thoroughly rolled and packed with 15-ton steam road-roller, until surface is ½" below finished roadway; spaces between stones then to be filled with fine screenings or binding gravel applied in at least 3 layers, each layer thoroughly worked in by wetting and rolling aforesaid before the next layer is applied, and during the operation the surface to be brought, with the broken stone, to a finished grade. **Crushed-Stone Sidewalk.**—Sub-grade 5" below finished surface of walk; on this, spread 2½" to 1" broken stone, making a 3" layer after rolling and ramming. On this, a layer of No. 2 crushed stone to be spread and thoroughly rolled to 2" thick. On this, spread a layer of fine screenings, trimmed, watered and rolled with steam, horse or hand rollers so as to make a hard, compact sidewalk at required grade. Edges to be supported by spruce plank if required.

THE PROPER CONSTRUCTION OF BRICK STREET PAVEMENTS.

(Will P. Blair†.)

Sub-Grade.—Must be drained, graded, compacted and parallel with grade of finished street; not essentially different than required for other pavements. A depression here and there, a spot of loose earth, a lack of thorough compaction, or a wet condition due to improper drainage will be followed by disaster to the street as a whole. **Foundation.**—(a) Impossible to define the proportions of cement, sand, broken stone or gravel that shall compose the mix, because of the varied qualities of these materials; but in order to secure maximum strength they must be mixed dry in the first instance, and then thoroughly mixed after the water is applied. (b) Either in the machine or hand mixing, an intelligent supervision is worth while at all times. The value of the concrete is often reduced at least 50% by carelessness, by ignorance or indifference, by application of too much or too little water, by lack of proper proportion of some one or another of the other ingredients composing the foundation, resulting in 1, 2, or 3 sq. yds. of the concrete foundation being of no more value than merely loose piles of stone or gravel. (c) The concrete surface as it is put in place must have a uniform surface with grade of finished street, and the surface must be smooth. This cannot be accomplished by the eye; the grade stakes should be set at no greater distance apart than 4 or 5 ft. If any stone used in the concrete exceeds 2" in largest diameter it will be next to impossible to accomplish the condition desired. Sufficient water should be used in the mixing so that one man can smooth the top with an ordinary dirt shovel—never should it be so stiff as to call into use a rammer. When we say "smooth surface" we mean that a greater variation than 1" shall not be allowed. **Sand Cushion.**—Must be 2" thick; if less, it will not afford a sufficient relief from the vibration created by the impact of travel; if more, it cannot be sufficiently compacted to afford a support to the load coming upon the brick street, and prevent cracking and crushing of the joints of the cement filler which is required in finishing the street. Thus, this cushion must be of such a thickness that will afford relief from the impact and weight, slight though it be, yet sufficiently unyielding to furnish the support for the load it must bear. **Expansion Cushion.**—This must be provided, after the sand cushion is spread, by

* See page 507.

† Secretary National Paving Block Manufacturers' Association.

ing next the curb a board of sufficient width to extend above the height of the brick; and in order that it may be drawn readily, it is advisable that wedge be dropped at intervals of 3 or 4 ft. behind this board and extending over it from 3" to 4"; the wedges to be $\frac{1}{2}$ " thick at top; the thickness of board varying with width of street, providing sufficient thickness ranging from to 1 $\frac{1}{2}$ ". **Laying.**—The brick should be placed in the street with the best edge up. This is a rule universally required of brick construction in masonry work. In order that this shall be done, the brick should be delivered to the person who drops them into the street with the face placed to suit the hand of the person, called the brick layer. The brick should not be laid in place in close contact with one another. Such practice will result in the brick being chipped, and it will be impossible to put in the cement filler properly in the interstices. **Inspection.**—After the bricks are placed, they should be inspected before being rolled so that as few bricks as possible will be disturbed after the rolling. **Rolling.**—The roller should be a light one, weighing from 4 to 5 tons; one that is easily handled, and can move rapidly upon the face of the brick. The rolling should proceed from each side along the curb, working toward the center of the street; then cross-rolling at angles of 45°; again rolling longitudinally and cross-rolling as before, continuing the process until the bricks are thoroughly compacted into the sand, so that the grade of the pavement shall be as intended and the inequalities of the surface ironed out by the sand being pushed up in the interstices of the brick, a condition always found in the case of properly rolled streets by an even amount pressed upwards in the interstices running from $\frac{1}{2}$ " to $\frac{3}{4}$ " and possibly 1" in some cases. (The use of the horse roller and the 8 to 10-ton arm roller should be prohibited). **Wetting.**—After rolling, the bad bricks should be replaced with good ones, the street swept clean, and then sprinkled, the use of a nozzle either upon a sprinkling can or a hose which will emit but the finest spray of water to come upon the street. **Cement Filler.**—The sand to be clean, sharp and dry; the mixing, not over $\frac{1}{2}$ bu. of sand and the amount of Portland cement, to be placed in box and mixed dry until the color is of even shade; water then added, forming mix. like thick cream. The mix should be kept in constant motion from time of mixing until floated into place. Mix. to be removed from the box to the street surface with a scoop shovel; box to be 3 $\frac{1}{2}$ to 4 ft. long, 27" to 30" wide and 14" deep, with one end low, and 8" to 10" above pavement. The mix., from the moment it touches the bricks, shall be thoroughly swept into the joints. Two boxes each provided where street is under 20 ft. wide; over 20 ft., 3 boxes. This work of filling should be carried forward in line until an advance of 15 to 20 ft. has been made, when the same force shall be turned back and cover the same space in like manner, except that the proportions for the *second coat shall be $\frac{1}{2}$ Portland cement and $\frac{1}{2}$ sand.* To avoid possibility of thickening at any point, there should be a man with a sprinkling can, the head perforated with small holes, sprinkling gently the surface ahead of the sweepers. Within $\frac{1}{2}$ to $\frac{3}{4}$ hour after the second coat is applied, and grout between joints fully subsided, and initial set is taking place, the whole surface is to be lightly sprinkled and all surplus mixture left on the tops of the bricks swept into the joints, bringing them up flush and full. Then, after sufficient time for evaporation has taken place, a $\frac{1}{2}$ " layer of sand shall be spread over the whole surface, and if under a hot summer sun, the sand should be watered occasionally for a few days.

CINCINNATI (OHIO) PAVEMENT SPECIFICATIONS.

BOULDER PAVEMENT.

Sub-Grade.—Brought to even surface, parallel with grade proposed for pavement, making necessary excavation and embankment. Soft or spongy material, etc., to be removed, and space filled with broken stone, rammed or rolled. Sub-grade surface to be compacted by rolling with steam roller weighing not less than 250 lbs. per lin. in. of roller; portions not accessible to be rammed. Finished sub-grade to be 14" below surface of pavement. **Grout.**—Upon the sub-grade thus prepared the entire surface of the roadway between the gutters will be spread evenly with a layer of sound, high quality limestone, broken into fragments as nearly regular as practicable, over 2 $\frac{1}{2}$ " dia.; the layer to be of such thickness that when thoroughly

This cushion to be composed of pitch or asphaltum composition, the middle third the allotted space. the remaining top third to be filled with sand.

compacted its surface shall be 6" above true surface of sub-grade, using roller above described. Where additional material is required, after rolling, to bring surface to proper grade, the rolled surface must be loosened to depth of 2" to receive the new material, and afterward rerolled. **Gravel Layer.**—On the broken-stone foundation, spread a layer of gravel, loose, and of sufficient depth in which to pave the boulders. The gravel must be clean and free from animal or vegetable matter or refuse; it must not contain more than 15% of clay or loam, nor pebbles exceeding 1" longest diameter. **Paving (General).**—In paving, the foundation work shall be kept laid to proper grade, rolled or rammed into proper slope or shape at least 100 ft. ahead of paving; be laid in sections of not less than 100 ft. in length, entirely free from gravel, rubbish, etc., and thoroughly swept, ready for inspection. **Boulders.**—The boulders will be laid down between the gutter-flagging; to be of good shape free from flaws or breaks, of hard, imperishable substance, no sandstone or limestone boulders to be used, no stone to measure less than 4" nor more than 6" in longest diameter; the stones to be carefully assorted and so placed that the largest shall be next the gutter-flagging and gradually diminish in size to the center. **Laying.**—No stone when set in an upright position, to show a horizontal diameter of less than 3" or more than 6" in any direction, and they must be set firmly on the foundation in a perfectly upright position, with small ends down, and as closely and compactly together as possible; none to be laid flat or on side edge. When boulders have been set for a distance of 60 ft., the first 50 ft. must be lightly rammed, after which a covering of gravel, sufficient only to fill the interstices, will be spread over the surface and thoroughly broomed in, when the whole will be thoroughly rammed with not less than 40-lb. rammers. When two sections (aggregating 110 ft.) have been treated, the first 100 ft. will be again covered with gravel, broomed, rammed, and ready for inspection. As soon as each section of 100 ft. is accepted, a final covering of 2" of gravel will be spread over the entire surface.

DETROIT (MICH.) PAVEMENT SPECIFICATIONS.

GENERAL.

Old Pavement and curbing to be measured to contractor as excavation; all old material and rubbish, including surface dirt, to be removed, city reserving curbing, etc. for new pavement, same to be delivered free by contractor to nearest city yard or for distance of 1 mile, if required. Contractor to use care in removal of old cushion sand to prevent mixture with other material. **Grading.**—After excavation to sub-grade, should there be places in street which are not firm, the earth must be taken out and the space re-filled with crushed stone and rolled. Before laying the concrete foundation and after the curbstone has been set, the sub-grade shall be rolled with 7-ton roller furnished and operated by City, at cost to contractor of $\frac{1}{4}$ c. per sq. yd. After this rolling, high places shall be brought to sub-grade and depressions filled with concrete at expense of contractor. Sub-grade to be properly planked before teaming is allowed. **Curb Trench.**—Trench to be excavated on each side of roadway to depth sufficient to set curb on concrete base 6" deep and of such width as to allow concrete backing to the curb of 4" thickness; bottom to be smoothly trimmed parallel to curb grade. **Stone Curbing.**—Old curbing taken up shall be rejointed, edges rounded, retopped, refaced and reset wherever directed, as per specifications for jointing, facing and setting new curb. New curb to be of best quality of granite, Medina, North River Blue, Elyria, Berea, or other curb as may be bid upon and ordered. The stone shall be 4" thick (ordinarily), at least 3 ft. long, and 18" deep; upper corner next to roadway to be rounded with radius of $1\frac{1}{2}$ ". Top and face of above-named stone curb to be dressed to what is known as 4-cut work, true and even, and the softer curb to be crandall dressed, true and smooth, all with close joints at the ends of at least 7" below top of curb, and a joint of not to exceed $\frac{1}{4}$ " for the remaining 18" depth of curb; stones to have straight and even face on gutter side to depth of 7" below top. Back of curb to be dressed 3" down from top. Top to be dressed to a straight line, and to $\frac{1}{4}$ " bevel in 5", and to uniform thickness or 4" (ordinarily). Stones to be taken out of wind, set with close joints to street line and grade on concrete bed 6" deep, and to full width of trench, and backed up with concrete to within 4" of top of curb; the remaining 4" behind curb to be filled with suitable earth well compacted. The crushed stone for concrete to be $\frac{1}{2}$ " to 1". **Concrete Curbing.**—Concrete for cement curb, plain or re-

forced with metal, shall consist of not more than 4 parts of 1" to $\frac{1}{2}$ " broken stone or slag, 2 parts sharp sand, and 1 part Portland cement; curbing to be of approved construction and finish. **Foundation.**—When the roadbed has been prepared, it shall be covered with a layer of concrete not less than 6" thick, and rammed until the surplus cement mortar appears on the surface, which shall be smooth and parallel to roadbed. No teaming allowed until set and covered with plank; defects to be repaired before work proceeds. **Concrete.**—Broken stone, 2" to $\frac{1}{2}$ ", may be from boulders, granite, syenite, slag, or hard limestone; it must be clean, screened if necessary to free it from dirt or stone refuse, and wetted before being placed on mixing boards. The concrete shall consist of 1 part natural cement, 2 parts sand, and 4 parts stone or slag; or 1 part Portland cement, 3 parts sand, and 6 parts stone or slag; depending upon which cement is specified.

BRICK PAVEMENT ON CONCRETE FOUNDATION.

Cushion.—Coat of clean, sharp, bank, lake or river sand, well screened, to be spread over concrete foundation to depth of $1\frac{1}{2}$ " when compacted. **Brick Paving.**—Shall consist of best quality of sound, hard, burned paving brick, or cement brick, made especially for street paving purposes, and to stand all reasonable tests as to durability and fitness, to which paving material is usually subjected. Bricks to be round or bevel-edged, straight, free from cracks and other defects, of uniform size, and of approved quality, equal to approved sample in office. **Handling and Piling Brick.**—Brick to be handled with brick tongs, carefully, to avoid breakage or chipping, and piled on street in rectangular piles, with uniform tiers or courses to aid counting. **Manner of Laying.**—Upon the cushion, the pavement to be laid with a single layer of brick on edge, end to end, in right angle or diagonal courses across the street, as may be directed, except at street intersections and along street railway tracks where the courses are to be placed at such angles as may be designated. Bricks to be set in straight courses, with body of bricks close together, sides and ends touching, and breaking joints at least 2" with the bricks in adjoining courses; to be set perpendicular to grade of street, and to height of from $\frac{1}{2}$ " to 1", or as may be directed, above the true grade and crown of street when finished, to allow for settlement in pounding and rolling. Whole bricks to be used, except in starting a course or in making a closure, when not less than half bricks may be used in breaking joints, tight and close at ends. **Rolling and Tamping.**—The paving when laid, and before filling of the joints and top dressing is put on, shall be rolled three or more times lengthwise of street, with not less than 7-ton roller, furnished and operated by City at $\frac{1}{2}$ c. per sq. yd. Parts which cannot be rolled shall be rammed. **Tar Filling.**—Whenever tar filler is specified, the joints to be filled to the bottom with paving cement obtained from the direct distillation of coal tar, and shall be residuum thereof, such as is ordinarily numbered 5 and 6 at the manufactory, or any other approved composition; quality and temperature to be approved. Extra material to be used at gutters, catch-basins, etc., to prevent leakage of water sub-roadway. **Grout Filling.**—A joint, $\frac{1}{2}$ " in width, next to and parallel the curbstone, to be filled to top with a composition of coal tar cement, mixed with at least 10% of refined asphalt, and the whole mixed with sufficient still wax to prevent softening or brittleness in hot or cold weather. Streets with car tracks, three rows of brick to be laid along outside of tracks in form of stretchers, with broken joints, and all joints filled with same composition. Balance of pavement to be filled with grout, composed of 1 part Portland cement and 1 part sand. The grout to be prepared in small quantities, stirred while being applied to pavement, and swept into joints with proper brooms; no settlings or residue to be used. Filling to be done in two or more applications of grout; the first $\frac{1}{2}$ " in depth from the bottom to be filled with grout somewhat thinner than required for the remainder; balance with a thicker grout, and if necessary refilled; brick to be freshly wet. Teaming and traffic prohibited for about one week. **Top Dressing.**—Surface of paving to be covered with $\frac{1}{2}$ " top dressing of sand. **Finishing Stone.**—At intersections with paved streets and alleys having a finished surface, the pavement shall be finished up to a Medina stone or 4" thick, not less than 16" deep, and not less than 30" long, to be set in concrete bed 6" deep, 8" wide and backed with 4" of concrete to within top. Stones to be dressed on top, pointed down on both sides to bottom of surfacing material, having good joint for depth of 3" from top, and to grade.

SHEET ASPHALT PAVEMENT ON CONCRETE FOUNDATION.

Binder.—Upon the concrete bed a binder course to be laid, composed of clean, broken stone, varying in size from fine to coarse, all to pass a $1\frac{1}{4}$ " ring in its larger dimensions. Stone after being heated shall not contain less than 5% nor more than 15% of material passing a No. 10 screen. Stone to be heated not higher than 350° F. in suitable appliances; then thoroughly mixed by machinery with asphaltic cement, such as is acceptable for surface cement; penetration, 60 to 90, at 77° F., City standard, at such temperatures and in such proportions that the resulting binder will have life and gloss without an excess of cement. Should it appear dull, from overheating or lack of cement, it will be rejected. While hot, it will be hauled upon the work and spread upon the base, so that when compacted it will be at least $1\frac{1}{2}$ " thick, and immediately rammed and rolled until it is cold. **Wearing Surface.**—Upon the binder course will be laid the wearing surface, or pavement proper, the binding material of which must be a cement prepared from asphalt, refined until free from water and volatile oils. This surface to be composed of asphaltic cement, clean, sharp-grained sand and fine absorbent mineral dust. The Asphaltic Cement must be prepared from refined asphalt of one of the following brands: Trinidad, Bermudez, Obispo, or any other equally as good. The refined asphalt shall be softened into a proper asphaltic cement by the addition of a suitable flux. The flux must be either a residuum from eastern petroleum oil, Texas petroleum oil, or a maltha from which the light oils and water have been removed by distillation. The asphaltic cement to be satisfactory, practically free from water, and within the range of 40 and 70 penetration (amount of penetration to be fixed by Department of Public Works), at 77° F., City standard. The Sand to be hard grained and moderately sharp. On sifting, it should have at least 15% caught on a 40 mesh to the inch screen; 25% pass an 80 mesh, 10% of which must pass a 100 mesh screen. If the sand used does not contain the desired fine material, mineral dust can be added to make up the deficiency, and in any case at least 5% of such mineral dust shall be used. The Mineral Dust shall be fine, absorbent inorganic dust, not acted upon by water, the whole of which shall pass a 30 mesh screen, and at least 75% pass a 100 mesh screen. The Asphalt Paving Mixture to be composed of above materials mixed in proportions by weight, depending upon their character and the street traffic and character of asphalt, and will be determined by the inspector; but the per cent bitumen in any mixture, soluble in carbon di-sulphide, shall not exceed the limits 9 to 13 per cent. Proportions of mixture must not be varied from those specified. The sand, or the mixture of sand and stone dust, and the asphaltic cement, shall be heated separately to about 300° F. The dust, if limestone, will be mixed while cold with hot sand, in the required proportions, and then mixed with the asphaltic cement at the required temperature and in the proper proportion, in a suitable apparatus, so as to effect a thoroughly homogeneous mixture. The mixture thus prepared will be brought to the street in carts, at a temperature of not less than 230° nor more than 350° F., depending on the asphalt in use; canvas covers to be used if the temperature of the air is less than 60° F. It is then to be spread to a thickness of at least 3" by means of hot rakes, to a uniform grade, so that when compressed it will have a finished thickness of at least 2". The surface to be compressed by rolling, after which a small amount of hydraulic cement will be swept over it, and it will then be thoroughly compressed by a steam roller weighing not less than 175 lbs. to the inch run, the rolling being continued for not less than 5 hours for each 1000 yds. of surface. Contractor to furnish a 10-year guarantee. **Retaining Stone.**—(Same as for brick pavement.)

CEDAR BLOCK PAVEMENT ON CONCRETE FOUNDATION.

Cushion.—(Same as for brick pavement.) **Cedar Blocks** to be 4" long, of best quality of sound, selected, live timber, stripped of all bark and free from traces of rot or indications of decay, and not less than $4\frac{1}{2}$ " nor more than 9" in diameter and so selected in size as to make a close-jointed pavement. **Filling.**—Spaces between blocks to be filled with screened gravel or crushed granite or boulders of size varying from $\frac{1}{2}$ " to 1" diameter and free from dust, sand, loam or thin stone, screened, when necessary, through a wire screen set at an angle of 60°, with meshes of not less than 8" lengthwise by $\frac{1}{2}$ " in width; tamped with iron tamping bars as required, and then the surface well rolled by City roller at cost to contractor of $\frac{1}{2}$ c. per sq. yd. After rolling

spaces between gravel or stone filling of the blocks to be completely filled from bottom to top with paving cement obtained from the direct distillation of coal tar, and shall be the residuum thereof, such as is ordinarily numbered 5 or 6. Quality and temperature to be approved. Extra care at gutters, catch-basins, etc. **Top Dressing.**—(Same as for brick pavement.) **Retaining Plank.**—Where cedar pavement is laid, the pavement at intersections of unpaved streets and alleys to be finished up to a piece of timber 3" thick and 12" deep, set on 6" of concrete, and extending across the proposed width of roadway of such street or alley. For all other kinds of pavement a stone header will be used, similar to, and set as stated for retaining stone. **Retaining Stone.**—(Same as for brick pavement.)

EASTON (PA.) PAVEMENT SPECIFICATIONS.

(John McNeal, City Engineer.)

MACADAM AND TELFORD ROADS.

Work.—Done by City force; not by contract. **Grading.**—Completed grade to have slope of from $\frac{1}{4}$ " to 1" per ft. from center to sides, according to percentage of grade of street. **Roadbed.**—Must be rolled firm with steam road roller; depressions formed by rolling to be filled and rolled again to finished sub-grade. **Macadam Foundation.**—On the sub-grade, place 3" to 4" crushed stone, spread evenly, and roll with road roller until none of the stones move under the roller; all material to be added dry, but water added ahead of the roller. This course to be 5" thick. **Telford Foundation.**—On the sub-grade, place the bottom course composed of stones 8" to 12" long, 3" to 4" wide, and 5" deep, vertically by hand on their broadest edges and pointed at the top; stones to be laid in lengthwise courses across the street, and all interstices filled with broken stone, wedged with a hammer; projecting points to be broken off to surface grade. This course to be thoroughly rolled until stones do not rock under the roller. Clay may be used as a binder on this course if directed. **Second Course.**—(Same for either macadam or telford.) On the foundation, lay a 3" course of crushed stone, $\frac{1}{4}$ " to $\frac{1}{2}$ ", and roll until firm and solid, water being applied ahead of the roller. **Binder.**—The binder for the bottom and second course shall be limestone screenings, applying water ahead of the roller if necessary. **Surface.**—On the second course, a coat of 50% of $\frac{1}{4}$ " stone and 50% of screenings, properly mixed, of about 1" thickness, shall be applied dry and rolled once before wetting, then alternate watering and rolling until finally completed, when the surface must be uniform to shape and grade. (The several courses of material shall be of required depth after rolling, allowance for compression being at least one-half.) **Rolling.**—Each course to be rolled with the utmost thoroughness, the roller starting from the sides and working toward the center.

CONCRETE CURBS, GUTTERS AND SIDEWALKS.

Fig. 3.—Concrete Curb, Gutter and Sidewalk.

ter sidewalk is excavated and shaped to proper depth and grade, the curb, gutter and sidewalk shall be constructed in place, upon a bed of gravel or cinders 8" to 10" deep, well consolidated by ramming to an even

surface, and moistened before the concrete is placed thereon. The curb, gutter and sidewalk to be composed of concrete formed by mixing dry, 1 part Portland cement, 2 parts coarse, clean sand and 4 parts clean screened limestone or trap rock, crushed to pass through a 1½" mesh screen, to which shall be added sufficient water to form a concrete that when placed in the templets and thoroughly rammed, free mortar will appear on the surface. The ramming of the concrete in the forms shall be done with the proper tamping bars and other tools to insure a compact mass with full square corners. All exposed surfaces to be covered with a finished coat 1" thick, composed of 1 part cement, 1 part clean, fine hard stone screenings, and 1 part clean, coarse sand, applied before concrete has hardened. Top facing of curb, gutter and sidewalk to be thoroughly troweled to insure perfect contact; when sufficiently hard it shall be troweled and floated to a smooth true surface. Concrete curb to be 6" thick at top, 8" at base, and 24" deep, exclusive of foundation. Concrete gutter to be 6" deep, 3 ft. wide on all streets more than 20 ft. wide, and 2 ft. wide on narrower streets; surface of outside edge to be grooved with 4" squares for width of 2 ft. on the 3-ft. gutters, and 1 ft. on 2-ft. gutters, to prevent slipping of horses. Concrete sidewalk to be at least 5" deep. For the entire depth of curb, gutter and sidewalk, joints to be made with tar paper or by means of removable plates to form expansion joints or planes of weakness; joints to be not more than 10 ft. apart.

REINFORCED CONCRETE FOUNDATIONS.

See article entitled "Reinforced Concrete Foundations over Excavations on Paved Streets," in Trans. A. S. C. E., Vol. LX, p. 217 (1908).

EL PASO (TEX.) PAVEMENT SPECIFICATIONS.

(F. H. Todd, City Engineer.)

PETROLITHIC PAVEMENT.

Preparing Roadway.—The roadway shall be so excavated or filled that after thorough rolling, or tamping with hand rammers at such points as cannot be well done with roller, its surface shall be 2" below and approximately parallel with surface of finished street. Soft and boggy places not affording a firm foundation shall be dug out, refilled and thoroughly tamped with good sound earth, cinders, gravel, slag, stone or concrete, as may be directed; the contractor to be paid for this excavation the same price as other excavation, if the soft and boggy place was not caused by him, but if caused by him, then at his own proper cost and expense. The entire roadway shall then be ploughed to a depth of not less than 6" nor more than 9", and thoroughly pulverized by cultivating, harrowing, or such other method as will accomplish the result. **Foundation.**—On this thoroughly pulverized roadway, including the intersections of all streets and alleys up to the property lines of the street being improved, the roadway shall be evenly coated with liquid asphalt, ½ gal. per sq. yd. of surface; it shall then be thoroughly cultivated to a depth of 6" until the liquid asphalt which has been applied is thoroughly mixed with the soil; then a second application of liquid asphalt, ½ gal. per sq. yd., shall be made and the area again well and thoroughly cultivated to a depth of 6", until the liquid asphalt and the material comprising the surface of the street are well and thoroughly mixed; then the third application of liquid asphalt, ½ gal. per sq. yd., shall be evenly spread over the entire roadway and the area for a third time well and thoroughly cultivated in such a manner that the liquid asphalt shall become thoroughly mixed with the street surface to a depth of 6". The street shall be thoroughly watered after each application of the liquid asphalt. The surface of the street shall then be brought to a grade approximately parallel to grade of finished street. **Tamping.**—The street shall then be tamped with a petrolithic rolling tamper until it is solid to within 2" of the surface. When the tamping of the road with the rolling tamper is begun, the rolling tamper shall be immediately followed by a cultivator set so as not to disturb the sub-base already tamped; said cultivator being reset as the tamping progresses, so as to cultivate to shallower depths. The cultivator shall be used continually during the tamping, the purpose being to prevent a too rapid solidification whereby the roadway would be solidified without being compacted from the bottom up. Upon this base prepared as above specified shall be applied liquid asphaltum, ½ gal. per sq. yd. of street surface. **Wear**

Surface.—On the foundation, shall be placed a layer of hard, durable, crushed stone, 2" to 1" screen, spread evenly and to such thickness that after it has been thoroughly sprinkled, and rolled with a roller weighing not less than 10 tons, its surface shall be parallel to and $\frac{1}{4}$ " below surface of finished street. Liquid asphaltum shall then be applied, $\frac{1}{2}$ gal. per sq. yd. of surface; then a layer of crushed rock, $1\frac{1}{2}$ " to $\frac{1}{2}$ " screen, shall be spread evenly to depth of $\frac{1}{2}$ "; then the surface shall be thoroughly watered and rolled, followed by a coating of liquid asphaltum applied at rate of $\frac{1}{2}$ gal. per sq. yd. then a light coating of rock screenings $\frac{1}{2}$ " and under in size, and in sufficient quantity to absorb all the surface liquid asphaltum and produce a uniform surface. The pavement shall then be watered and rolled until it becomes hard, smooth, true to grade and cross-section, free from all hollows and other irregularities, until but slight movement takes place under the action of the roller. In streets or avenues having a street-railway track, the street shall be excavated to a point 6" below the ties and 6" beyond the end of the ties, and this space filled with broken stone or slag to the upper surface of the ties; this filling to be so well tamped with stones of assorted sizes, from 3" in greatest- to $\frac{1}{2}$ " in least dimension, that but slight movement will take place under the ties during the passage of the electric car. The space between the rails shall then be filled in the same manner as is provided for wearing surface on other portions of the street. It will be necessary, however, to provide a roller so formed as to make the flange-ways similar in form to that approved by the City Council, Jan. 9, 1908. With this roller, the surface of the street between the rails must be so compressed that but slight movement takes place under a 10-ton road roller. That portion of the roadway outside of the rails, shall be treated in a manner similar to the wearing surface of the remaining portion of the street. In case rock is encountered in excavating, it will be necessary to remove that to a depth of at least 3" below finished surface of street.

Liquid Asphaltum.—The liquid asphaltum used shall contain not less than 76% of asphaltum at 80° penetration when tested at a temperature of 77° F. The specific gravity shall not be lower than 1.0° or higher than 1.1° Baumé, at a temperature of 60° F., and shall not contain more than 2% of water and sediment. In all cases the liquid asphaltum shall be applied at a temperature between 200° and 250° F. It shall be applied to the roadway by an approved form of sprinkler, such as will give a uniform distribution over the entire surface of the roadway.

Concrete.—The cement shall be equal in quality to the best American Portland cement, and opportunity shall be provided to test it for 30 days before it is used in the work, in order to prove its strength and soundness. The Sand, for mortar, must be clean, sharp, and have grains of different sizes so proportioned as to make a good aggregate. The Concrete, for pavement foundation or street railway foundation, must be made from 1 part by measure of Portland cement, 3 parts sand, and 7 parts clean, sound, hard, broken rock, or clean gravel, of various sizes from $2\frac{1}{2}$ " in greatest- to $\frac{1}{2}$ " in least dimension, and these sizes so proportioned as to give the greatest density. Measuring Boxes shall be provided, if required. After the cement, sand and rock or gravel have been thoroughly mixed dry, either by hand or machinery, it shall be wet in such manner as not to wash away the cement, and at the same time the mixing shall be done so that the wet particles of cement and sand are thoroughly incorporated as mortar, and each stone covered with mortar, the whole mass being in it *just enough* water to make the concrete, when in place, slightly *ropy*. From the time water is first applied to the batch until the concrete is thoroughly rammed in place, the work must proceed rapidly and the mixing must be so well done that no voids remain in the concrete, and the *flushes* to the surface. Before the concrete sets, but after it is rammed hard, enough hard, clean, broken stone, $2\frac{1}{2}$ " to 1", to about cover $\frac{1}{2}$ " of surface shall be evenly spread on it. These stones shall then be rammed hard into the concrete to hold them firmly and yet leave it rough enough to securely hold the petrolithic wearing surface. The Concrete shall be composed of 1 part Portland cement, $2\frac{1}{2}$ parts sand, and 3 parts clean, hard, durable broken stone, $\frac{1}{2}$ " to 2" in greatest dimension and in proportions as to give the densest mixture, and placed in the same manner as specified for concrete foundation. After the concrete has been thoroughly rammed in the gutter, and while it is yet soft, $1\frac{1}{2}$ " of mortar composed of 1 part Portland cement and 2 parts sand and as much fine crushed stone as will make the densest aggregate, shall be placed on top and well tamped, after which the surface shall be finished with the proper tools to accurately conform to the given lines and grades. Proper forms shall be provided for all concrete work. Expansion Joints of roofing paper

and bitumen, or of bitumen alone, must be provided and placed at such place and in such manner in the concrete as may be required, but not more than 20 ft. All concrete work shall be covered with earth and after it has set and shall be kept wet for at least 1 week and shall be protected from injury for at least 10 days after laying, to allow it to set properly.

Marginal Curb.—Whenever a paved street is joined to an unpaved street, a marginal curb of hard, durable stone at least 15" deep, 5" thick, and 2 ft. long and with top surface broken to a straight line, must be provided and set, if required. This curb shall be set in 6" of the same class of concrete specified for foundation, and backed up with the same to within 6" of top. The upper surface must conform to the cross-section of the street.

General.—The price bid per sq. yd. for complete petroliithic pavement shall include the excavation or filling required to bring the street to its established grade and surface, and further, must include the furnishing, placing and manipulation of all material necessary for the construction of this pavement including all labor and necessary implements. No wearing surface shall be laid when the temperature of the air is below 40° F., and preferably, if asphaltum for the foundation and surface shall be applied during warm dry weather.

LOS ANGELES (CAL.) PAVEMENT SPECIFICATIONS.

(Homer Hamlin, City Engineer.)

GRAVELED STREETS.

(Oiled.)

Sub-Grade.—For the roadway, shall be 4" below surface of finished work unless otherwise indicated or directed. **Grading.**—Shall include all filling, excavation, shaping and trimming required to bring surface of street to its grade and cross-section. Mud and other soft material, to a depth of 2 ft. shall be taken out and the space filled with good earth or gravel. All filling to be with good sound earth; the embankment to be carried up of full width in horizontal layers, not over 1 ft. thick, the teams to travel as evenly as possible over the whole surface of each layer, both going and coming. After the street has been brought to the required grade and cross-section, the surface shall be thoroughly moistened and rolled with a roller weighing not less than 250 lbs. to the inch width of tire, until it is unyielding. Depressions made by the rolling shall be leveled up with good earth and again rolled. Such portions of the street as cannot be reached by the roller, and all places excavated below grade and refilled, and all pipe trenches and other places that cannot be properly compacted by the roller, shall be tamped solid, and in case of wet weather or soft or muddy ground, making the use of the roller unsafe or impracticable, the rolling shall not be undertaken until the ground has become sufficiently dry. The sub-grade shall then be tested for grade, cross-section and condition. **Surfacing Roadway.**—Upon the sub-grade, spread a layer of good gravel, to have a thickness of 4" (ordinarily) after rolling. The surface of this layer for a depth of 1" is to be raked free from all stones larger than 1" in greatest dimension. If no gutters are provided, the larger stones shall be raked to the curb and distributed over a strip 2 ft. width next to the curb; if gutters are provided, the stones are to be distributed on a strip 2 ft. wide next to the gutter. This layer of gravel is to be uniformly spread on the roadway, and well moistened; then well rammed for at least 1 ft. from the gutters, should these be paved; or if not paved then 1 ft. from the curb. The remaining portion of the roadway shall then be rolled with a roller weighing not less than 250 lbs. to the inch width of tire. The rolling of roadway shall commence at the rammed portion. All depressions must be promptly filled, moistened, and again rolled. The sprinkling and rolling must continue until the surface is uniformly hard, compact, and in such condition that it will not yield or cut up under the wheels of a heavily loaded wagon. **Oiling.**—Oil shall then be distributed evenly over the entire surface of roadway, 1 gal. per sq. yd. Coarse, sharp sand shall then be sprinkled over the entire surface of roadway until no free oil can be seen. After a lapse of not less than 12 hrs., oil shall again be distributed over entire surface, $\frac{1}{2}$ gal. per sq. yd. Entire surface of roadway shall again be sprinkled with coarse, sharp sand until the oil is completely absorbed, and then rolled with a roller weighing not less than 250 lbs. to the inch width of tire until the surface is unyielding. In all cases, sufficient sand shall be used to prevent the oil material from picking up. Total amount of oil used shall not be less than $1\frac{1}{2}$ gals. per sq. yd. of street surface. In procedure

of rolling, care must be taken not to soil the curbs or walks. After the oiling has begun, it shall be carried on diligently and continually to its completion. Sand used in covering the oil must be distributed in piles along the sides of the street before the oil is applied, and must be spread quickly and in sufficient quantity to prevent the oiled surface from picking up. Oil shall not be applied to the surface of a street while in a wet condition. During and immediately after rolling, the surface of the street shall be gone over with brooms or rakes and all irregularities removed.

Oil.—(a) The oil used shall be a natural oil treated to remove water or sediment, or one from which the volatile material has been removed by distillation. It must not have been injured by over-heating, and it must not be obtained by adding solid asphalt to lighter oils, or by cutting asphalt with distillates. (b) Temperature. All oil must be delivered at the point required or sprinkling, at a temperature not less than 150° F. (c) Measurement. In determining the quantity of oil delivered, the correction for expansion by heat shall be as follows: 60° F. shall be considered normal temperature; subtract 0.0004 of measured volume for each °F. above 60° F., as a correction for expansion by heat. (d) Volatility. The oil shall not contain more than 8% of matter volatile when said oil is heated slowly to 220° F. and maintained at that temperature for 15 minutes. (e) Asphalt. After being freed from water and sediment, the oil shall contain not less than 70% of asphalt, having a temperature of 77° F., a penetration of 80°, District of Columbia standard. The percentage of asphalt shall be determined by heating a weighed amount of said oil in an evaporating oven to a temperature of 400° F. until it has reached the proper consistency, when the weight of the residue shall be determined and the per cent calculated. (f) Water and Sediment. Reduction will be made for water and sediment in exact proportion to the percentage of water and sediment found therein, which must not exceed 2%. (g) Tank wagons. All tank wagons used for the delivery of this oil must first be submitted to the Department of Oil Inspection, which will gauge and stamp into the steel heads of said tanks the capacity in gallons, which shall be the official rating. (h) All oil used shall be tested by the Department of Oil Inspection.

Surfacing Sidewalk Areas.—In cases where the plans provide for cement sidewalks on portions of the street to be improved, and do not provide for sidewalks over its entire length, then there shall be constructed at the accepted places gravel walks 2" deep and of a width and location corresponding to those for the cement walk provided for. In cases where the plans do not provide for cement walks on the street to be improved, then gravel sidewalks 2" deep and 5 ft. wide shall be constructed, except, however, in cases where the total width of the sidewalk area is less than 5 ft., in which event the total area of the sidewalk is to be graveled. In the construction of the graveled walks, the same quality of material as that used in the roadbeds shall be employed. It shall be raked free from large stones, sprinkled and bed until firm.

BITUMINIZED BRICK GUTTERS.

Sand Cushion.—Upon the concrete base (the surface of which is 6" below finished grade, and thoroughly watered for at least 48 hours, before receiving the cushion coat, and swept free from all dirt and rubbish) shall be spread a layer of sand 2" deep. The sand need not necessarily be sharp, but it must be clean, dry and free from more than 3% of loamy matter. It shall be laid by the aid of a templet and made to conform smoothly to the true line of the gutter. There shall be no disturbance of the surface of the cushion coat previous to laying the bituminized brick thereon. **Laying Bituminized Brick.**—Upon the cushion coat shall be laid the bituminized bricks, vertically on edge, and in close contact with each other. Brick in starting rows must be laid so as to break joints at least 2". No bats or pieces of bricks shall be used except for the purpose of closure or for breaking up in starting courses. After the bricks are laid they shall be thoroughly tamped and all warped, spalled and chipped brick removed and replaced by perfect ones. The edge of the gutter next the curb shall then be carefully tamped by hand and the whole gutter shall then be rolled until all bricks are thoroughly bedded and the tops lie in a smooth surface conforming to the grade and cross-section of gutter. Asphalt of a composition hereinafter specified, and heated to a temperature of 300° F., shall then be poured into the gutter until they are full and remain full to height of top of brick. Surplus asphalt shall then be removed, before it has become stiff, from the surface of

the gutter, and fine sand shall be swept over the top until all stickiness is removed. **Bituminized Brick.**—Shall be obtained by subjecting ordinary brick of the quality specified hereinafter to a bath of asphalt, also of the quality hereinafter described, and heated to a temperature of from 300° to 325° F., until at least 80% of the cross-section of the brick shall have become saturated with asphalt. They shall be free from warps, cracks, chips or other flaws, and the surfaces shall be free from superfluous asphalt and in condition to lay closely together. All bituminized brick will be subject to the following **Abrasion Test.**—This test shall be made in a foundry rattler whose inside diameter is 28" and inside length is 20". Such a number of whole, dry brick that their total volume shall equal, as nearly as possible, 8% of the cubic contents of the rattler, shall be placed therein. There shall then be added an abrasive charge of 300 lbs. of cast iron blocks as follows: 10 blocks about 2½" square and 4½" long, with edges rounded to about ½" radius and weighing 7½ lbs. each, and 225 lbs. of cubical blocks about 1½" on a side and with square corners and edges. The rattler shall be revolved 1800 times at a speed of from 28 to 30 rev. per min. The loss by abrasion during such test shall not exceed 20% of the original weight of the brick. **Ordinary Brick.**—Shall be whole, sound brick with smooth, rectangular surfaces and straight edges and must give a clear ringing sound when struck together. They shall be uniform in quality, free from laminations, and shall run in size from 8" to 8½" long, 4" wide and from 2" to 2½" thick and burned to a medium degree of hardness. All brick shall be culled or sorted by the contractor before being treated to an asphalt bath, and will be subject to the following test: Three or more bricks shall be broken across, thoroughly dried, weighed, then immersed in water for 24 hours and weighed again. The absorption shall be determined by the difference between the two weights, and it shall not exceed 15% nor be less than 12% of the dry weight of the brick; otherwise the brick from which the tested samples were selected, shall be rejected. **Asphalt.**—This must be prepared from California products. It shall be a mixture of refined liquid asphalt with a refined solid asphalt or be an oil asphalt, and must be free from admixture with any residues obtained by the artificial distillation of coal, coal tar or paraffine oil. The asphalt must be homogeneous and its consistency at the time of its use in the bath must fall within the limits of 60° and 80° penetration by the District of Columbia standard. It must be adhesive and ductile and also slightly elastic at a temperature of 32° F. When 20 grams are heated to a temperature of 300° F. for 5 consecutive hours in an uncovered cylindrical dish 3½ cm. high by 5½ cm. in diameter, it must not lose more than 1% in weight, and its penetration must not be reduced, as a result of such heating, more than 50%. It must, when ready for use, contain at least 90% of bitumen soluble in carbon disulphide. It shall be soluble in cold carbon tetrachloride to the extent of at least 97%. Not less than 70% shall be soluble in 86° naphtha. It shall not contain more than 15% of fixed carbon on ignition. When the asphalt is prepared by mixing a solid oil asphalt with a liquid asphalt, the solid oil asphalt shall be prepared by distilling the crude oil until the asphaltic residuum has a penetration not less than 50° by the District of Columbia standard, and shall not be prepared by mixing or fluxing a more solid asphalt with a liquid or softer asphalt. The refined liquid asphalt used in softening a solid asphalt must be a stiff residuum of petroleum oil with an asphalt base. It must be free from water and from light oils volatile at less than 250° F. When 20 grams are heated to a temperature of 300° F. for 5 consecutive hours in an uncovered cylindrical dish 3½ cm. high by 5½ cm. in diameter, it must not lose more than 5% in weight. It must contain not less than 99% of bitumen soluble in carbon disulphide.

MARYLAND STATE HIGHWAY SPECIFICATIONS.

(Maryland Geological Survey.)

MACADAM CONSTRUCTION.

Class A, B and C.—Thickness after rolling, to be as follows:

Class A.	1st course, 3";	 2nd, 3";	 3rd, as described later.
Class B.	"	5", in 2 layers;	" 3";
Class C.	"	5", gravel;.....	" 3", stone; " "

Roadbed.—Natural earth bed prepared and rolled until firm and hard; a small amount of clay to be added if sandy or other soil will not compact readily under roller. In Cuts and Fills, roadbed is to be graded 24 ft. wide

Roadbed prepared for broken stone surface to be 14 ft. wide* and rolled firm and hard; depressions filled with earth and rerolled. Old earth roadbed, where there is no change in grade, is to be shaped to proper cross-section, elevations and depressions removed, and surface rolled hard and smooth. The portion of the roadbed prepared for the broken stone, is to be below the sides by an amount equal to thickness of 1st course of stone, to prevent spreading at sides. Roadbed to have cross-slope of $\frac{1}{4}$ " to 1 ft. **First Course.**—Sound broken stone, 3" to 2", known as "No. 1" size. If approved it may be gravel, 3" to 1", with not more than 25% less than 1". No layer of crushed stone to be spread thicker than 6" before being thoroughly rolled. Broken stone or gravel for 1st course to be rolled with steam roller weighing not less than 10 tons, until compacted firm and smooth; sprinkling with water or lightly spreading with sand if needed; rolling to begin at sides and work toward center. Unevenness or depressions to be remedied. **Shoulders.**—After 1st course is made, construct shoulders along each side for width of at least 5 ft.; against these shoulders, spread broken stone for second course; the shoulders with the 14 ft. of broken stone will make a total width of 24 ft., to be cross-sloped $\frac{1}{4}$ " to 1 ft. **Second Course.**—Same width as first course. Broken stone 1" to 2", known as No. "2" size. Unless otherwise specified the stone for this course shall be trap rock with a "coefficient of wear" as determined by tests made at the laboratory of the Highway Division of the Maryland Geological Survey, of not less than 15, or limestone with a "coefficient of wear" of not less than 10. The broken stone to be spread upon the 1st course, to a uniform thickness, and rolled with not less than a 10-ton roller, sprinkling with water or lightly spreading with sand or other material if necessary, until surface is hard and smooth; cross-slope of surface, $\frac{1}{4}$ " to 1 ft. Unevenness and depressions to be remedied. **Third Course.**—Trap rock screenings, from 1" to dust; other material may be used if approved; limestone screenings to be used with a limestone 2nd course. Upon the 2nd course, and in quantity just enough to cover it, the screenings are to be spread dry, then sprinkled with a sprinkling cart, and rolled with not less than a 10-ton roller, beginning at the sides. If after rolling the screenings, the No. 2 stone appears at the surface, use additional screenings. Rolling and watering to continue until the water flushes to the surface; the rolling to extend over whole width of road and shoulders. Unevenness and depressions to be remedied.

NATIONAL ASSOCIATION OF CEMENT USERS.

(Philadelphia, Pa.)

PORTLAND CEMENT SIDEWALK SPECIFICATIONS.

(Adopted January, 1908.)

Materials.—(1) Cement shall meet requirements of specification for Portland cement of the A. S. T. M., and adopted by this association (Spec. No. 1), January, 1906. (2) Sand shall pass a No. 4 screen and be free from foreign matter, except loam and clay up to 5% when not occurring as a coating on sand grains. Not more than 40% shall be retained on a No. 10 sieve; or 70% pass a No. 10 and be retained on a No. 20; or 35% pass a No. 20 and be retained on a No. 30; or 35% pass a No. 30 and be retained on a No. 40; or 70% pass a No. 40 and be retained on a No. 50. Not more than 20% shall be retained on a No. 50 sieve; or 70% pass a No. 10 and be retained on a No. 40; or 70% pass a No. 20 and be retained on a No. 50 sieve. (3) Stone shall be shed from clean, sound, hard, durable rock, be screened dry through a mesh, and be retained on a $\frac{1}{4}$ " mesh. (4) Screenings from the crushed stone, if they meet the requirements for sand, may be used as sand if approved. Gravel shall be clean, hard, and vary in size from $\frac{1}{4}$ " to $\frac{1}{2}$ " screening; uncrushed gravel shall be clean, hard, and contain no particles larger than $\frac{1}{4}$ ", proportions of fine and coarse to be determined and corrected to agree with requirements for concrete. (5) Water to be clean, free from oil, sulfuric acid and strong alkalis. **Forms.**—(7) Lumber, free from warp, not less than 1 $\frac{1}{2}$ " thick; all mortar and dirt to be removed from forms previously used. (8) **Setting.**—The forms shall be well staked to the established lines and grades, and their upper edges shall conform with finished

* Mr. E. F. Ruggles, First Assistant Engineer, writes the author as follows: "As a rule, our roads are built with a width of 12 ft. for the macadam; though we have built, where the travel requires it, a good deal of 14-ft. macadam."

grade of sidewalk, which shall have sufficient rise from curb to provide proper drainage; this rise not to exceed $\frac{1}{4}$ " per ft., except where such rise shall parallel length to walk. (9) Cross Forms, at each block division, shall be put in the full width of walk and at right angle to side forms. (10) Expansion Joints. A metal parting strip $\frac{1}{4}$ " thick shall take the place of the cross-forms at least once in every 50 lin. ft. of sidewalk. When sidewalk has become hard, this parting strip shall be removed and joint filled with suitable material prior to opening the walk to traffic. Similar joints shall be provided where new sidewalks abut curbing or other artificial stone sidewalk. (11) Wetting. All forms to be thoroughly wetted before any material is deposited against them. **Size and Thickness of Blocks.**—(12) In Business Districts, blocks shall be so divided that no dimension shall be greater than 6 ft.; thickness of sidewalk shall correspond directly with the greatest dimension of the walks as follows: 6" thick for block 6 by 6 ft.; 5 $\frac{1}{2}$ " for block 5 by 5 ft.; 5" for block 4 $\frac{1}{2}$ by 4 $\frac{1}{2}$ ft.; 4" for block 4 by 4 ft. (13) In Residence Districts, thickness of sidewalk shall be as follows: 6" thick for block 6 by 6 ft.; 5" for block 5 by 5 ft.; 4" for block 4 by 4 ft.; 3" for block 3 by 3 ft.; it being permissible to lay sidewalks with a thickness at the edges 25% less than at center. (14) Minimum Thickness of walk to be 3" in any case. **Sub-Base.**—(15) Preparation. Sub-base to be thoroughly rammed, and all soft spots removed and replaced by suitable hard material. (16) Fills. When a fill exceeding 1 ft. thick is required, it shall be thoroughly compacted by flooding and tamping in layers not over 6" thick, and shall have a slope of not less than 1 to 1 $\frac{1}{2}$. The top of all fills shall extend at least 12" beyond the sidewalk. (17) Wetting. While compacting, the sub-base shall be thoroughly wetted and shall be maintained in that condition until the concrete is deposited. **Base.**—(18) Proportions. The concrete for the base shall be so proportioned that the cement shall overfill the (19) Voids* in the sand by at least 5%, and the mortar shall overfill the voids in the stone by at least 10%. The proportions shall not exceed 1 part cement to 8 parts of the other materials. When the voids are not determined, the concrete shall be: 1 part cement, 3 parts sand or screenings, and 5 parts stone or gravel. A sack of cement (94 lbs.) shall be considered to have a volume of 1 cu. ft. (20a) Hand Mixing. Spread sand evenly on level water-tight platform; spread cement upon sand; mix thoroughly dry to uniform color; add water in a spray, and turn mass until homogeneous mortar of even consistency is obtained; to this mortar, add the required amount of stone or gravel previously drenched, and mix the whole until the aggregate is thoroughly coated with mortar. When unscreened gravel is used, the cement and gravel shall be thoroughly mixed dry until no streaks of cement are visible; water shall be added with a spray in sufficient quantity to render when thoroughly mixed, a concrete equal to that specified above. Water may be added during the process of mixing, but the concrete shall be turned at least once immediately after its addition. (20b) Mechanical Mixing. Machine mixing will be acceptable when a concrete equal in quality to that specified above is obtained; mixing to be thorough. (21) Retempering will not be permitted. (22) Depositing. The concrete shall be deposited within 1 hour after being mixed, and shall be transferred to the forms in water-tight wheelbarrows; the barrows not to be filled so full as to allow mortar to slop out, and shall not be run over freshly laid concrete. The concrete to be spread evenly and tamped until water flushes to the top. (23) Separation of Blocks shall be done with a tool not over 6" wide and $\frac{1}{4}$ " thick, and to insure

* To determine voids, fill a vessel with sand and let net weight of sand equal B. Fill same vessel with water and let net weight of water equal A.

$$\text{Per cent voids} = \frac{A \times 2.65 - B}{A \times 2.65} \times 100.$$

This formula may also be used in determining voids in crushed stone and screenings by substituting for 2.65 the specific gravity of the stone.

The following is a more simple method of determining voids in coarse aggregate: Fill a vessel with the aggregate and let net weight equal B. Add water slowly until it just appears on the surface, and weigh. Let net weight equal A. Fill same vessel with water and let net weight equal C.

$$\text{Per cent voids} = \frac{A - B}{C} \times 100.$$

Use a vessel of not less than one-half (1) cubic foot capacity. The larger the vessel, the more accurate the results.

complete separation the groove should be cut through into the sub-base. Fill the groove with dry sand before the top coat is spread, and the top coat should be cut through to the sand after floating and troweling and a jointer run in the groove; then again draw a trowel through the groove, so as to insure a complete separation of the block. (24) Protection. Workmen not permitted to walk on freshly laid concrete, and where sand or dust collects on the base it shall be carefully removed before the wearing surface is applied. **Wearing Surface.**—(25) Thickness. $\frac{3}{4}$ ". (26) Mixing. The mortar to be mixed in the same manner as the mortar for the base, but using 1 part cement to 2 parts of sand or screenings, and it shall be of such consistency as will not require tamping, but will be readily floated with a straight-edge. (27) Depositing. Spread mortar on the base within 30 minutes after mixing, and in no case shall more than 50 minutes elapse between the time that the concrete for the base is mixed and the time that the wearing course is floated. Float a thin coat of mortar on the base before spreading the wearing surface. (28) Marking. After being worked to an approximately true surface, the block markings shall be made directly over the joints in the base with a tool which shall cut clear through to the base and completely separate the wearing courses of adjacent blocks. (29) Edges. All surface edges of blocks to be rounded to radius of not less than $\frac{1}{4}$ ". (30) Troweling. When partially set, the surface shall be troweled smooth. (31) Roughening wearing surface. On grades exceeding 5%, the surface shall be roughened, by using a grooving tool, toothed roller, brush, wooden float or other suitable tool, or by working coarse sand or screenings into the surface. (32) Color. If color is desired, only mineral colors shall be used, which shall be incorporated with the entire working surface. **Single Coat Work.**—(23) Proportions. Single coat work shall be composed of 1 part cement, 2 parts sand, 4 parts gravel or crushed stone, and the blocks separated as provided for in the specifications for two-coat work. (34) Finishing. The concrete shall be thoroughly compacted by tamping and evenly struck off and smoothed to the top of mold. Then, with a suitably grooved tool the coarser particles of the concrete tamped to the necessary depth so as to finish the same as two-coat work. **Protection and Grading.**—(35) Protection. When completed, the sidewalk shall be kept moist and protected from traffic and the elements for at least 3 days; the forms to be removed with great care, and when removed, earth shall be banked against the edges of the walk. (36) Grading, after the walks are ready for use, should be on the curb side of the sidewalk, $1\frac{1}{2}$ " lower than the sidewalk, and not less than $\frac{1}{4}$ " per ft. fall toward the curb or gutter. On the property side of the walk, the ground should be graded back at least 2 ft. and not lower than the walk; this will insure the frost throwing the walk alike on both sides.

MANHATTAN (N. Y. CITY) BOROUGH PAVEMENT SPECIFICATIONS.

GRANITE BLOCK PAVEMENT.

Blocks.—Shall be of a durable, sound and uniform quality of granite; 6" to 12" long, $3\frac{1}{2}$ " to $4\frac{1}{2}$ " wide, and 7" to 8" deep; same quality as to hardness, color and grain. No outcrop, soft, brittle or laminated stone accepted. Blocks to be rectangular on top and sides, uniform in thickness, to lay closely, and with fair and free surfaces, free from bunches. Other dimensions of blocks may be used for special construction. Stone from each quarry shall be piled and laid separately in different sections of the work; no mixing of stones from different quarries. **Sand Cushion.**—On the concrete foundation previously prepared 6" thick place a layer of clean, coarse, dry sand to such a depth (not less than $1\frac{1}{2}$ ") as may be necessary to bring the surface of pavement when thoroughly rammed, to the proper grade. **Laying.**—On this sand bed, and to grade and crown specified, lay the blocks at right angle to line of street, or at such angle as may be directed; each course to be straight and regular, with the end joints by lap of at least 3"; stones of different width not to be laid in the same course, except on curves; joints to be close, except where gravel filling is used the joints between courses shall not exceed $\frac{1}{4}$ ". After the blocks are laid, they shall be covered with clean, hard and dry gravel (previously heated and dried), to be brushed in until the joints are filled therewith to within 3" of the top; the gravel to be washed white quartz, free from sand or dirt, and $\frac{1}{4}$ " to $\frac{1}{2}$ " mesh screenings. **Ramming.**—Blocks must then be rammed and ramming repeated until they are brought to an unyielding bearing with a uniform surface, true to even grade and crown; no ramming to be done within 20 ft. of face of work being

laid. **Joints.**—After ramming, the pavement cement heated to 300° F. shall then be poured into the joints until same are full and remain full to top of gravel. Hot gravel shall then be poured along the joints flush with top of blocks; and paving cement again poured in joints, filling all voids. **Paving Cement.**—Shall be composed of 20 parts of refined asphalt and 3 parts of residuum oil, mixed with 100 parts of coal-tar pitch such as is ordinarily numbered 4 at the manufactory, the proportions to be determined by weight.

WOOD BLOCK PAVEMENT.

Foundation.—6" thick, including 5½" of concrete proper and ½" of mortar top surface, ordinarily. **Blocks.**—(a) Either of southern long-leaf yellow pine, southern black gum, Norway pine or tamarack, not less than 90% of heart; texture permitting satisfactory treatment; inspection at works, in the stick, before being sawed into blocks. (b) All blocks shall be of sound timber, free from bark, loose or rotten knots, or other defects detrimental to life of blocks or to laying; no second-growth timber allowed. (c) Blocks shall be well made, rectangular and of uniform dimensions: Depth (parallel to fiber) 3½", length 6" to 10", width 3" to 4"; in any one contract, blocks to be of same timber, and depth and width shall not vary more than ¼". (d) Blocks to be treated with an antiseptic and waterproof mixture, not more than 75% per cent of which shall be creosote or heavy oil of coal tar, and at least 25% of which shall be resin; all parts of each block to be thoroughly treated, injecting not less than 20 lbs. per cu. ft. (e) Treated pine blocks shall weigh as much as water; treated gum blocks, at least 59 lbs. per cu. ft.; any other wood, at least 20 lbs. per cu. ft. more than its recognized weight untreated. Blocks cut from the several classes of timber will require different treatment, hence the exact methods of applying the mixture will not be specified, but must conform in every respect to the best and most advanced knowledge of the art. (f) The creosote oil at 68° F. shall have a specific grav. of not less than 1.12; when distilled in a retort with the thermometer suspended not less than 1" above the oil, it shall lose not more than 35% up to 315° C., and not more than 50% up to 370° C. Oil to be free from adulteration or foreign material. (g) The resin to be solid resin obtained from pine; and reduced to a fine dust by grinding and then incorporated with the hot creosote oil in a suitable mixing tank until the proper proportions are secured. (h) After treatment, blocks not to gain more than 8½% in weight after being oven-dried at 100° for 24 hours and then immersed in water 24 hours. **Analysis of Treated Block.**—Fine turnings from the block shall be placed in an extraction apparatus and the oil completely extracted therefrom with ether or carbon bisulphide; the oil then placed in a still and distilled; the portion up to 120° C., consisting of the solvent, is to be collected apart; the oil then distilled up to 370° C. The oil thus obtained must conform in all respects to the requirements of (h), above. **Mortar Bed.**—On concrete foundation, spread ½" layer of mortar composed of 1 part Portland cement to 4 parts clean, sharp sand, free from pebbles over ½" diameter; the mortar top to be "struck" 3½" below and parallel to top of finished pavement. The mortar bed to be laid as follows: On surface of concrete foundation, before mortar bed is laid, set strips of wood 4" wide by ½" thick, or strips of steel 4" by ½", and of convenient length; these strips to be set parallel and about 8 to 10 ft. apart, running from curb to curb, and imbedded in mortar so that top surface shall be 3½" below grade of finished pavement; the space between two strips having been filled with mortar, a true and even top surface shall be struck by using an iron-shod straight-edge on the strips as a guide, the strips to be removed and the places filled with mortar as the blocks are laid. **Laying.**—On this mortar surface the blocks are laid, with the grain vertical, in parallel courses, at angles as directed, tight joints as possible, each block being firmly imbedded in the mortar bed so as to form a true and even surface. Expansion joints, ½", shall be used along each curb, and across the street every 100 ft. The joints shall then be filled with cement grout (2 parts sand and 1 part Portland cement, mixed to a perfectly liquid form) and the surface of the blocks shall be slushed with same and joints swept until completely filled; surface then covered with ½" of screened sand. **Grooved Blocks.**—Where grade exceeds 3%, the blocks shall be between 6" and 10" long, the upper edge of each block to be cut away for a width of ½" and depth of 1", so as to provide transverse grooves between each course (as a foothold for horses); or other equally good construction. Blocks to be laid (in usual manner), 4" lap, whole blocks used, and covered with sand when laid.

RICHMOND (N. Y. CITY) BOROUGH PAVEMENT SPECIFICATIONS.

(Louis L. Tribus, Commissioner.)

IRON SLAG BLOCK PAVEMENT.

Blocks.—Iron slag blocks, 8" to 9" long, 3½" wide, 3" deep; shall be hard, durable and perfect; upper edges to be chamfered. On grades of 6% or over, the joints between blocks are to be left open to receive hot, clean gravel, with paving cement; for grades below 6%, the joints will be laid close without gravel but filled with paving cement. **Sand Cushion.**—On the foundation (concrete) place about a 2" layer of clean, dry sand to bring surface of pavement, when rolled, to proper grade; sand to be screened and free from stones and rubbish; cushion to be brought to required form andrown by means of template resting on curbs and drawn forward a few feet, head of laying. **Laying.**—Blocks laid on edge at right angle to curb line, except at street intersections where they shall be laid as required. End joints to be broken by lap of half length of block. At every 4th course, or as often as directed, blocks shall be closed up by hammering and the course straightened. End joints to be closed by means of crowbar applied at ends next the curbs before the closures are made. Whole blocks used except in beginning or closing a course, or as directed. **Rolling.**—As soon as street rock has been laid, the pavement shall be swept clean and rolled with 5-ton roller until all blocks are thoroughly imbedded in the sand cushion; all depressed surfaces to be relaid; pavement then rerolled until finished surface smooth and even, to required grade and crown. Broken or chipped blocks to be replaced. **Expansion Joints.**—Before laying the blocks, laths ½" thick shall be placed next each curb. The spaces thus formed shall be filled with hot paving cement composed as follows: **Paving Cement.**—Shall be bituminous material either natural or artificial, free from coal tar or any products of coal tar distillation. It shall be waterproof, free from water or composition products, remain ductile and pliable at all climatic temperatures to which it may be subjected in actual use, and shall not run in the streets in the hottest temperature in summer, nor become hard and brittle through the action of frost. It shall conform to the following requirements: 6% or over by weight shall be soluble in carbon bisulphide; specific gravity 16° F. to be not less than 1; 100 grams of this cement not to lose more than 10% weight when maintained at a uniform temperature of 400° F. for 24 hours in a cylindrical vessel 3½" diameter and 1" high; amount of fixed oil not to be more than 12% and it shall show a flashing point, open oil test, of more than 510° F., and shall not contain more than 2½% of paraffin scale; if obtained by mix of bituminous materials, it shall be homogeneous, free from water and light oils, obtained by agitation with hot air at temperature of not more than 400° until all the mass is blended completely, and shall be free from granular accumulations. Penetration test: 25° F. with No. 2 needle and 100 grams weight for 5 seconds, shall not be more than 1 millimeter; at 115° F., No. 2 needle, 50 grams, not less than 8 mm. or more than 15 mm.; ¼ gram of the material when made into a ball shall melt and drip through an aperture 1 mm. in diameter at less than 220° F. Paving cement shall be heated on the work to a temperature between 400° and 450° F., in quantities to allow this temperature to be maintained in the joints during progress of pouring; none with temperature below 400° to be used. It shall then be put in a conical can and poured in the interstices between blocks till the filler is flush with top of blocks; repeating filling if necessary. All joints between blocks shall be filled with this hot paving cement, pouring from center to sides, but no flushing of the pavement will be permitted. Where girder rails are used, the space between the web of rail joining blocks shall be filled with mortar, composed of Portland cement and sand. **4. Underdraining.**—Pipes shall be vitrified, salt-glazed stoneware set with proper collars, pipes to be 4" inside diameter and 12" to 24"

VITRIFIED BRICK PAVEMENT.

Bricks.—The carriageway to be paved with best quality of repressed paving blocks made of shale or clay, and with ½" lugs on the sides; uniform in size, color and quality and of same make; blocks to be from 2½" wide, 7" to 10" long, and 4" to 4½" deep, exclusive of projection. Selected (34 blocks of average quality from each 50000 or less) to be subjected to the following tests: Bricks to be free from lime and magnesia in the form of pebbles and shall show no signs of cracking or spawling on reboiling in water 96 hours; when subjected to tests for abrasion, loss in

RICHMOND (IND.) STREET CROWNING.

(H. L. Weber, City Engineer.)

 Crowning is parabolic: $h_1 = \frac{H}{9}$; $h_2 = 4h_1 = \frac{4}{9} H$.

 Fig. 5.—Diff. between g and H —diff. in elev. bet. curb and crown levels.

* Crowning is calculated for $H = 7\frac{1}{2}$ " at curb line; and level of crown is $1\frac{1}{2}$ " above level of curb.

† Half width of street to be used on side next to stone curb. Crowning is calculated for $H = 6$ " at curb line; and crown is level with curb.

‡ Half width of street to be used on side next to cement curb; and crown is level with curb.

SYRACUSE (N. Y.) PAVEMENT SPECIFICATIONS.

(H. C. Allen, City Engineer.)

GENERAL.

Excavation.—Includes earth, rock or other material necessary to be removed from work, to depth required to reach sub-grade, and work connected with adjusting street intersections and grading slopes back of curb line. Excavations below sub-grade shall be made up with cement concrete. Surplus material shall be deposited within an average distance of 2000 ft., or disposed of by contractor. **Embankment.**—Shall start from a well-prepared base, mellowed or stepped on sloping ground, and be carried up in horizontal layers not over 4" thick, each layer carefully rammed or rolled, and well watered. **Rolling and Ramming.**—After the sub-grade has been brought to the surface prescribed, it shall be rolled with steam roller of not less than 5 tons, until surface is firm and compact. Portions inaccessible to roller shall be rammed, and all depressions, defects, etc., made by the contractor, and again rolled and rammed.

VITRIFIED BRICK PAVEMENT.

Concrete Foundation.—Upon the sub-grade thus prepared, lay a bed of portland cement concrete 6" deep, of 1 part cement, 3 parts sand, 6 parts broken stone. Use best quality of Portland cement; sand to be clean, coarse and sharp, free from foreign matter; broken stone to consist of hard durable material, varying in size from $2\frac{1}{4}$ " to $\frac{1}{2}$ " in diameter, and free from dust or dirt. **Bedding.**—Upon the concrete foundation, thoroughly set and dry, carefully lay a $\frac{1}{2}$ " layer of clean, coarse, sharp sand, or fine screened gravel, free from dirt or vegetable matter; leaving surface true and even and parallel to grade. **Paving Bricks.**—Shall be made and burned especially for street

paving purposes, and shall stand all reasonable tests as to durability and fitness, to which paving material is usually subjected; the material to be burned in down-draught kilns or furnaces. Bricks to be square and straight, with sharp or slightly beveled edges, free from cracks or other defects, and of uniform size and pattern, and approved quality, equal to approved samples; specific gravity not less than 2. Size may be: length $7\frac{1}{2}"$ to $8\frac{1}{2}"$, width $2\frac{1}{4}"$ to $2\frac{1}{2}"$, depth $3\frac{1}{4}"$ to $4"$. The absorption of water by any one brick to be not greater than 3%; average absorption of all bricks tested not to exceed 2% of their dry weight; tests to be made on either abraded or broken bricks by drying them for 12 hours in an oven and then soaking them 12 hours in water. At least three bricks shall be used for this test. The bricks shall also be tested in the standard rattler* and by the method of the National Brick Manf. Assn. and Am. Soc. of Municipal Improvements. **Sample Bricks.**—Three or more bricks of the kind or quality to be used on the paving shall be furnished with each proposal; the bricks to be labeled with bidder's and maker's names and addresses. **Manner of Laying.**—Upon the cushion, the pavement to be constructed with a single layer of bricks, laid on edge, end to end, in courses at right angles with the curb line, except at street intersections, where courses are to be placed at such angles as directed. Bricks to be set in courses across the street, which must be kept true and parallel, with the body of the bricks close together, sides and ends touching, and breaking joints at least $3"$ with bricks in adjoining courses; they are to be set perpendicular to grade of street, and to a height of from $\frac{1}{4}"$ to $\frac{1}{2}"$ (ordinarily) above the true grade and crown of street when finished, to provide for settlement in pounding. Whole bricks to be used except in starting and closing courses at curbs, catch-basins and street structures, when not less than half bricks may be used in breaking joints, which shall be tight and close at ends. **Ramming and Tamping.**—The paving when laid, and either before or after the filling of the joints and top dressing is put on, as may be directed, shall be thoroughly rammed not less than three times with a paver's rammer of 90-lb. weight; the blows of the rammer must not be made directly on the bricks, but upon a $2"$ plank not less than 10 ft. long and $12"$ wide, which will be laid upon the surface of the pavement, which must conform to true grade and crown of street. **Grout,** composed of equal parts Portland cement and sand, with proper amount of water, to be poured upon the pavement and swept to and fro until every joint is filled flush with the surface of the pavement, and continued until joints are entirely filled. Wet sand then to be spread over the entire pavement $\frac{1}{2}"$ thick, and kept wet until ordered removed.

SANDSTONE BLOCK PAVEMENT.

Concrete Foundation.—(Same as for vitrified brick pavement.) **Cushion.**—Upon the concrete foundation, thoroughly set hard, carefully spread $2"$ layer of clean, coarse sand, free from loam, dirt or vegetable matter; leaving surface true and even and parallel to grade. **Sandstone Blocks.**—Shall be of best quality of Medina or Potsdam sandstone, not less than $3"$ nor more than $5"$ thick, not less than $6"$ nor more than $7"$ deep, and from $7"$ to $12"$ long; must be sufficiently dressed to present rectangular faces with straight edges on top, bottom and sides, and all blocks whose faces vary more than $\frac{1}{4}"$ from the rectangular shape will be rejected. The sides and ends of the blocks must be so dressed that they will make joints not to exceed $\frac{1}{4}"$ in width. If necessary to obtain a satisfactory surface, the top surface of the blocks to be cut or "axed" off smooth, sides and ends to receive similar treatment when necessary to secure the $\frac{1}{4}"$ joint. The stones to be set tight together, perpendicular to grade, so as to break joints at least $2"$, in uniform rows across the street at right angles to line of curb, except at street intersections and other places as may be directed. When laid, the blocks to be carefully rammed as may be directed, with a paver's rammer, no iron being allowed on its lower surface to come in contact with the pavement, which is to be surfaced by using a long straight-edge; shall conform to established grade and crown. **Grout Filling.**—Pour into joints a Portland cement grout composed of 2 parts clean, sharp sand to 1 part Portland cement, of approved quality, together with enough water to make proper grout, which will be poured upon the pavement and swept to and fro until every joint is filled flush with surface of pavement, operation to be continued until joints are entirely filled. Wet sand then to be spread over entire pavement $1"$ thick, and kept wet until ordered removed.

* See page 507.

ASPHALT SHEET PAVEMENT.

Upon the concrete foundation, thoroughly set and hard, shall be laid the wearing surface, which is divided into two classes of standard grade sheet asphalt: Refined Asphalt and Rock Asphalt. It is intended to admit the use of any asphalt of reputation which can be made into a suitable paving mixture.

Refined Asphalt Sheet Pavement will consist of (1) refined asphalt (an asphalt after it has been freed wholly or in part from water or organic matter by being heated); (2) a hydro-carbon flux or softening agent; (3) sand and fine powder of carbonate of lime. **Asphaltic Flux.**—Properties required are: It shall contain no material volatile under 300° F.; shall be chemically stable and not lose its fluidity by molecular change; shall dissolve the asphalt and not simply form a mechanical mixture with it; must not volatilize more than 5% when heated for 7 hours at 325° F. The flash points shall be taken in a N. Y. State closed oil tested. **Asphaltic Cement.**—The refined asphalt is to be combined with the flux to produce asphaltic cement, to be tested as follows: Must not flash below 350° F.; must contain no water; must not show more than 4% loss by weight on being heated at 325° F.; and must not show a loss of more than 8½% in weight on being heated 7 hours at 350° F. It must not contain more than 4½% of carbonaceous matter insoluble in carbon bisulphide, and must not show more than 15% of fixed carbon, and must not contain more than 3% of paraffine scale. The test for consistency of penetration of the asphaltic cement shall be the distance expressed in $\frac{1}{100}$ of a centimeter that a No. 2 needle will penetrate into it at 25° C. (77° F.) under a weight of 100 grams in 5 seconds of time, the needle to penetrate direct without friction. **Sand.**—Sand used for body of wearing surface shall be clean and sharp and composed of grains not easily crushed. Shall be graded in size of grains to reduce voids to a minimum, to secure which, a quantity of powdered carbonate of lime, from 5 to 15%, shall be added. The sand and grains to be graded in size about as follows: Retained on 10 mesh per inch, 3%; on 20 mesh, 5%; 40 mesh 25%; 60 mesh 25%; 80 mesh 12%; 100 mesh 18%; passed 100 mesh, 12%; total 100%. **Mixing.**—The wearing surface of graded aggregate and sufficient asphaltic cement to fill the voids when laid shall contain no trace of coal-tar, water, appreciable amount of light oils, no matter volatile at a temperature of 250° F. It shall yield, when extracted with bisulphide of carbon and after evaporation of the solvent, not less than 9½% nor more than 13% of bitumen, and at least 68% of the extracted bitumen shall be soluble in petroleum naphtha. The sand and asphaltic cement to be heated separately to about 300° F. The pulverized carbonate of lime, while cold, will be mixed with the hot sand in the required proportion and then mixed with the asphaltic cement at the required temperature, and in proper proportion, in a suitable apparatus, so as to effect a thoroughly homogeneous mixture. Sand boxes and tar and asphalt gauges will be weighed up daily. **Laying.**—Pavement mixture thus prepared will be laid on the foundation (same as for vitrified brick pavement) in two coats: the first, or cushion coat, will contain 2 to 4% more asphaltic cement than is required for the surface mixture, and laid so as to give a thickness of $\frac{1}{4}$ " after being consolidated by rollers. The second, or surface coat, prepared as required, to be laid on the cushion coat; it will be brought to the ground in mats at a temperature not less than 250° nor more than 300° F., and if the temperature of the air is less than 50° the contractor must provide canvas covers for use in transit; the mixture to be spread with hot iron rakes to form grade, and to have thickness of 2" after ultimate compression. The surface to be compressed by a hand roller, after which a small amount of hydraulic cement will be swept over it, then thoroughly compressed with a heavy steam roller, continued as long as it makes an impression on the surface, at least 5 hours for each 1000 sq. yds. of surface. **Gutters.**—Strip of cement 12" wide next to curb, to be coated with hot pure asphalt, and smoothed with hot smoothing irons, price to be included in price for pavement.

Rock Asphalt Pavement.—Shall consist of one or more natural bituminous stones or bituminous sandstone rocks. If necessary, they are to be mixed either with a quantity of natural asphalt added to secure proper proportion of bitumen, between 9 and 10%. A bituminous limestone shall be coarse-grained, as nearly as possible a pure carbonate thoroughly and evenly impregnated with asphalt, with no more impurities than the standard German asphalt of Limmer or Vorwohle. **Laying Pavement.**—(1) The lumps of asphalt to be crushed and pulverized and the powder passed through a fine

sieve. (2) This powder to be heated in a suitable apparatus to a temperature of about 200° F., and brought to the ground at such temperature, in carts, and spread on the concrete foundation (same as for vitrified brick pavement) previously prepared. (3) Then skillfully compressed by heated hand rollers and rammers until it shall have required thickness of $2\frac{1}{2}$ ". (4) Surface then made even by heated smoothers. (5) Finally, after completion, to be rolled with a heavy roller at least 5 hours for each 1000 sq. yds., a small amount of hydraulic cement to be swept over the surface during rolling.

CREOSOTED WOOD BLOCK PAVEMENT.

Concrete Foundation.—(Same as for vitrified brick pavement.) **Mortar Bed.**—On the foundation, spread a $\frac{1}{2}$ " bed of Portland cement mortar, 1 part cement and 2 parts sand, surfaced true and smooth and parallel to finished grade and cross-section. **Blocks.**—Long-leaf yellow pine, 50% heart, treated as described below; blocks to be of sound timber, free from bark, sap wood, loose or rotten knots, etc.; no second-growth timber to be allowed. Blocks not less than 3" wide, 5" to 9" long and 4" deep, uniform in depth and thickness; to be treated throughout with an antiseptic and water-proofing mixture as follows. **Treatment of Blocks.**—Mixture shall contain 50% of dead oil of tar, known as creosote oil; its specific gravity shall not be less than 1.12 at 68° F., it shall lose not more than 40% when distilled in a flask or retort for 30 minutes up to 600° F. The distillate to contain 4% tar acids and at least 12% naphthalin. Specific gravity of residue obtained by distilling the mixture up to 600° F. must be at least 1.15. After treatment, specific gravity of block shall be greater than that of water; and shall show such waterproof qualities that, after being dried in an oven at a temperature of 100° for 24 hrs., weighed and then immersed in water for 24 hours, the gain in weight not to be greater than 3%. Blocks to be treated as follows: Blocks to be placed in an air-tight cylinder, and when doors are closed the dry heat is to be raised to 215° F. without pressure, for 1 hour, to get rid of moisture. Then heat to be increased, pressure to be applied and both are to be raised gradually to avoid injury to fiber, for 2 hours, until heat has reached about 285° and pressure about 90 lbs., and both are to be held there for 1 hour. The heat is then to be shut off and the tanks allowed to cool gradually for 1 hour; then heat reduced to 250° and pressure to about 40 lbs. Pressure is then blown off and heat still further reduced. Vacuum is then applied until about 26" is raised, and while under vacuum the creosote mixture (which shall contain no tar, petroleum, or petroleum residue) is to be run into the cylinders at a temperature of 175° to 200°, and hydraulic pressure is to be applied, reaching 200 lbs. per sq. in., and kept at this point until 20 lbs. of the mixture per cu. ft. has been absorbed. The liquid is then run off, and the wood placed in another cylinder and milk of lime at a temperature of about 150° is run in and hydraulic pressure of about 200 lbs. applied for from $\frac{1}{2}$ to 1 hour. The antiseptic and waterproof mixture shall not contain more than 2% water at any time. The quantity specified for each tar acid, naphthalin and residue is the minimum for each. **Laying Blocks.**—Blocks to be set immediately upon the cement mortar bed, before it has set, and driven together as closely as possible. Pavement to be constructed with a single layer of the blocks laid on edge, with grain vertical, end to end in courses at right angle with the curb line except at street intersections where the courses are to be placed as directed. Blocks to be set in courses across the street; must be kept true and parallel, sides and ends touching, and breaking joints at least 3" with blocks in adjoining courses. Only whole blocks to be used except in starting and closing courses. **Expansion Joints** of bituminous cement to be placed at curb lines and across the street at intervals of 50 ft. Gutter joints to be 1" and cross joints $\frac{1}{2}$ ". To make these, a plank shall be inserted and the blocks laid against it; the plank then removed, and the crack thus left filled with bituminous cement which shall have a temperature of at least 300° F. Pavement then to be rolled with a hand roller until tops of blocks are even. **Bituminous Cement** used shall not flow at 120° F., and shall not become brittle at 0° F.; shall be proof against street liquids, and pliable rather than rigid. **Filling Joints.**—After pavement is rolled, bituminous cement heated to at least 300° F. shall be poured along, filling each crack, and only when blocks are dry.

BITULITHIC PAVEMENT.

Foundation.—Bituminous, or concrete. **Bituminous Foundation.**—On the sub-foundation, crushed hard limestone which will pass a $3\frac{1}{2}$ " ring, to be spread to a depth of 6", and compressed with heavy steam roller. On

this, after rolling, spread a heavy coating of Puritan brand bituminous cement, to make foundation unite with bitulithic wearing surface: One gallon of the cement to each sq. yd. of foundation. **Concrete Foundation.**—(Same as for vitrified brick pavement.) **Wearing Surface.**—On the foundation, lay the wearing surface, composed of carefully selected, sound, hard, crushed trap or syenite rock, mixed with bitumen, as follows: After heating stone in rotary mechanical mixer to temperature of about 250° F., it is elevated and passed through a rotary screen, having sections with various size openings; difference in width of openings in successive sections not to exceed $\frac{1}{4}$ " in sections with openings less than $\frac{1}{4}$ ", and not to exceed $\frac{1}{2}$ " in sections with openings more than $\frac{1}{4}$ ". The several sizes of stone thus separated by the screen sections shall pass into a bin with sections corresponding to screen sections. From these, the stone is drawn into a weigh box, resting on a scale having seven beams; the stone to be weighed, using the proportions previously determined by laboratory tests to give the best results; that is, the most dense mixture of mineral aggregate, and one having inherent stability. If the crushed stone in the wearing surface does not provide the best proportions of fine-grained particles, such deficiency must be supplied by the use of not to exceed 25% hydraulic cement, pulverized stone, or very fine sand. From the weigh-box each batch of mineral aggregate, of different sizes weighed as above, shall pass into a "twin pug," or other approved form of mixer. In this mixer shall be added a sufficient quantity of Puritan brand bituminous waterproof cement, to coat all the particles of stone and to fill all voids in the mixture. Before mixing, the bituminous cement shall be heated to between 200° and 250° F., and the amount in each batch shall be weighed and used in such proportions as have been determined. Mixing to continue until the combination is a uniform bituminous concrete. In this condition it is to be hauled to the street, and spread on the prepared foundation to such depth that, after compression with a steam road roller, it shall have a thickness of 2". The proportioning shall be such that the compressed mixture shall have the density of solid stone, as nearly as practicable. **Surface Finish.**—After rolling the wearing surface, spread over it, while it is still warm, a thin coating of quick-drying bituminous flush coat composition, by means of a suitable flush coat spreading machine provided with a flexible spreading and adjustable device for regulating the quantity and uniformity of the composition. On grades of over 4% a mineral flush coat may be used in place of the liquid flush coat. While the flush coat is still warm, spread over, in at least two coats, fine particles of hot crushed stone, in sufficient quantity to cover the surface of the pavement; these stone chips to be spread by means of a suitable stone spreading machine, so designed as to provide a storage receptacle of at least 5 cu. ft. capacity and to rapidly and uniformly cover the surface of the pavement properly. The hot stone chips to immediately be rolled into the surface until it has become cool. **Patents.**—Agreement of Warren Bros. Co., on file with City Engineer, to license all contractors desiring to bid for the work to lay bitulithic pavement in accordance with its patents.

TORONTO (ONT.) PAVEMENT SPECIFICATIONS.

(C. H. Rust, City Engineer.)

A.—GRADING.

Excavation.—Levels and cross-sections may be varied to conform to sills buildings, grades of intersecting streets, lanes, carriage ways, etc. **Trenches, etc.**—Trenches or excavations that have been made for or in connection with sewers, private drains, gas or water pipes, telephone or electric wires, pipes or conduits, street or other railway works, or any other lawful purpose, and which are not thoroughly settled, shall be opened out and re-filled with gravel, well pounded, in layers of not over 4"; no extra allowance to be made for contractor. **Defective Places.**—Soft, boggy, wet, muddy or defective places shall be wholly removed and filled with gravel, as in above clause, with no extra allowance. **Boulders, Trees, Etc.**—Boulders, stones, rocks, stumps, trees, etc., to be removed when directed, without extra pay. **Excavations low Grade.**—Where excavation is made below proper level of sub-grade, it shall be made up with concrete where foundation is concrete, or with gravel in all other cases, without extra pay. **Rolling, Etc.**—Sub-grade to be rolled with steam roller weighing not less than ... tons; to be omitted when engineer shall consent in writing. Portions inaccessible to roller shall be rammed. **Repairs, etc.,** to be repaired, and again rolled or rammed. **Engineer**

reserves privilege of testing sub-grade with City Roller. **Slopes.**—In cuttings, excavation to be made for a sufficient distance above and behind curbing, to form a slope of 2 horizontal to 1 vertical. **Oil Macadam.**—Where a macadam or broken stone roadway has to be excavated, the old material must be picked out and screened separately, and the stone delivered by contractor where directed, within 1 mile, without pay; extra haul at $\frac{1}{4}$ c. per cu. yd. per 100 ft.

B.—CEDAR BLOCK PAVEMENT.

Character of Pavement.—When gravel; sand or broken stone is used for foundation, it must be watered, rolled, rammed and consolidated, until quite hard and compact, using a 12 $\frac{1}{2}$ -ton roller, unless a lighter one is allowed. **Blocks.**—Shall be of first-growth, sound white cedar, stripped of bark. No pin hole more than $\frac{1}{4}$ " diameter, and not more than 3 pin holes allowed on wearing surface of block. Blocks from 5" to 11" in diameter, and shall not show more than $\frac{1}{4}$ " of sap wood at any part of outside edge. **Laying.**—After blocks are laid, they shall be rammed with a pounder of 80 lbs. or more, 12" diameter and flat on bottom. The whole surface then rolled with a roller weighing at least 5 tons. When pavement has been brought to surface, it shall (unless other filling is called for) be covered with a sufficient quantity of gravel to fill all joints, being worked in with suitable brooms. Surplus material, if any, then to be swept off, and pavement to be rammed as before. To be repeated if necessary. Finally, pavement to be covered with $\frac{1}{2}$ " layer of good clean gravel. **Board Bed.**—Shall be laid upon the foundation bed if required. Shall be pine, 9" to 12" wide, perfectly sound, etc.; and thoroughly swabbed on both sides and ends with approved composition, or dipped in same, or other preservative process. Where double boards are used, the lengthwise boards shall be 12 and 16 ft. in length, respectively, laid so as to break joint. **Concrete Bed.**—When a concrete bed is required it shall be laid as specified under "C.—Concrete," below. After the bed has set hard, spread a layer of clean, sharp sand so that it will be $\frac{1}{2}$ " thick after the blocks are laid upon it and rammed. **Grouting.**—When grout filling is required between the blocking it shall be composed of 1 part Portland cem., 3 parts coarse, sharp, clean sand, thoroughly mixed and flooded, and swept into all joints; repeating same until joints are full and flush with surface. Surface then to be covered with at least $\frac{1}{2}$ " layer of approved gravel. **Tar Filling.**—When tar composition is required for filling, it shall be composed of 1 part coal-tar to 2 parts pitch, boiled and freed from moisture, and applied at a temperature of 250 to 275° F., filling all joints. A paving pitch, when approved, may be used instead, and applied similarly, or as directed. **Clean gravel, $\frac{1}{2}$ " to $\frac{3}{4}$ ", dried and heated, must be used with above composition; the gravel to be swept into the interstices hot, and the composition applied at once, completely filling joints and flushing to surface. **Composition and Gravel.**—With board foundation, use not less than 2 gallons (imperial) of composition per sq. yd. of pavement; without board foundation, use not less than 3 gallons, and as much more as needed to fill flush to top of pavement. After ramming, pavement to be swept clean, and covered with hot composition, upon which shall immediately be spread heated gravel or stone chippings, $\frac{1}{2}$ " to $\frac{3}{4}$ ", at least $\frac{1}{2}$ " deep.**

C.—CONCRETE.

Proportions.—Upon the sub-grade, lay a bed of concrete, ins. thick, composed of 1 part best Portland cement, 3 parts clean, sharp sand, 7 parts broken stone or furnace slag; the proportions may be varied to 1 part cement and 10 parts of the sand, broken stone and slag. Gravel may be required instead of broken stone.

D.—ASPHALT PAVEMENT.

Kinds of Asphalt.—Use best quality of following asphalt: Trinidad, Bermudez, Venezuela, Natural Rock, California, or other equally as good, and approved. No coal-tar, or any other product thereof, or any other inferior products, will be accepted. **Cushion Coat.**—When light asphalt is specified no binder or cushion coat will be required. When heavy asphalt is specified a binder course 1" thick will be laid directly on the concrete foundation, but it will not be required where Natural Rock asphalt is used. This underlayer to be rolled and consolidated, while fresh and hot, with a steam roller weighing not less than 5 tons, to a finished thickness of 1". No binder asphalt to be laid during wet weather. **Should Rock asphalt be used it should be at least 2" thick. Surface Coat.**—Shall be 2" thick after ultimate compression.

E.—BRICK PAVEMENT.

Foundation.—A base of Portland cement concrete 4" or 6" in depth. **Cushion.**—Where no thickness is shown, the depth of sand will be at least 1½". **Paving Bricks.**—Must not be less than 2½" by 8½" by 4". **Paving Blocks.**—Must not be less than 3½" by 8½" by 4". Tests shall be made for absorption and abrasion. **Laying.**—(Usual manner.) **Ramming and Rolling.**—First with 80-lb. rammer, then with 5-ton roller. **Grout Filling.**—Composed of equal parts best Portland cement and sand, mixed; water added, stirred and immediately used, filling joints to no more than half their depth. Then thicker grout, 2 cement to 1 sand, for balance of joint. **Sand Coating.**—Not less than ½".

F.—MACADAM ROADWAY.

Foundation Course.—Upon the sub-grade, lay a course of stone, 5" in thickness; stones to be laid by hand, largest sides down, and in line at right angle to the curb, and breaking joint as much as practicable. The upper surface of stones not to be less than 6" nor more than 9" in width, nor less than 12" nor more than 15" in length. The stones to be set close together and bound by wedging in small stones and filling the interstices with stone chipping so as to form a compact bed. Stones projecting above the surface must be broken off, great care being used not to loosen the foundation. No wedging is to be done within 20 ft. of the work being laid. Next, spread evenly over this course, clean gravel to fill all interstices, and then roll and re-roll until thoroughly consolidated. **Intermediate Course.**—Upon the foundation, place a layer of broken stone, as granite, trap, or hard limestone, of approved quality. Not more than 5% of the stone shall be less than 1½" and no particle of stone shall be more than 3" in breadth. After this course has been evenly spread over the street (and raked if necessary) so as to present a uniform surface, a layer of coarse, clean sand is to be spread upon it, sufficient to fill voids, and the surface then watered (if necessary) and rolled, more sand and stone being applied where and as required, and the rolling and watering continued until an even, hard and uniform surface is obtained, after which the sand is swept up and removed from the surface. **Top Course.**—Consists of broken stone, ins. in depth, as uniform in size as possible, no particle to be more than 2½", and not more than 5% to be less than 1½" in length or breadth. The surface shall be raked evenly, watered, rolled, repaired, brought fully up to grade, and then re-rolled until firm, compact and true. A sufficient layer of good, coarse, clean sand is then spread over the surface, rolled, and flooded with water, to carry the sand into all interstices; more sand to be added as rolling and watering progresses, so as to have finished thickness of ½" to 1".

K.—CONCRETE SIDEWALK.

Foundation.—After the street has been graded, a foundation shall be laid, composed of coarse gravel or suitable soft coal cinders, to a depth of 4", after being consolidated by pounding or rolling with a suitable and approved roller, weighing at least 1 ton, and the whole brought to an even surface. Whilst pounding, a small quantity of water may be used through a sprinkler, directed. **Templates.**—When required, the contractor must furnish wooden templates, cut to exact form and slope of the walk, for use by the

Fig. 6.—Cross-section.

spectors. **Concrete Base.**—Upon this foundation, a layer of concrete, 3½" thick, shall be laid, composed of 1 part Portland cement (of approved quality), 2 parts of clean, sharp, coarse sand, and 5 parts of approved furnace

slag, broken stone or screened gravel, thoroughly free from stone over 2" diameter, and free from clay, loam, dirt or other impurities. The concrete thus made shall be rammed with iron rammers into one solid mass, and until it has a straight and even surface. **Divisions.**—Every 6 ft. a cut shall be made completely through the concrete before it is set, with an iron for that purpose, not less than $\frac{1}{2}$ " in width. The opening shall then be filled in with clean, sharp sand. A clear space not less than $\frac{1}{2}$ " must be left between back of curbing and abutting ends of sidewalks to allow room for expansion, excepting where the walk and curb are combined. **Heavy Surface.**—On the concrete base, before it has had time to set, lay the wearing surface, $1\frac{1}{2}$ " thick, composed of 1 part Portland cement, 1 part clean, sharp, coarse sand, and 3 parts crushed granite or quartzite. **Light Surface.**—On the concrete base, before it has had time to set, lay the wearing surface 1" thick, composed of 1 part Portland cement, 1 part clean, sharp, coarse sand, and 3 parts of screened pea gravel, crushed granite, quartzite or suitable hard limestone. (See Fig. 6.)

D.—CARE OF ROAD SURFACES.

DUST PREVENTIVES.*

CLASSIFICATION.

Two classes: 1st, water, salt solutions, certain light oils and tars, and oil and tar emulsions; 2nd, the heavier oils, tars, semi-solid and solid materials. Salt solutions are valuable because the dissolved salt has a considerable affinity for water and keeps the road moist long after a surface treated with water alone would have become dry. The light oils and tars, and oil and tar emulsions, leave upon the road surface a comparatively small amount of true binding base after the volatile products have evaporated. The heavy oils and tars contain a greater amount of binding base, hence more lasting. The semi-solid and solid preparations usually contain a still greater amount of binder, and also other materials of a solid nature, such as rocks, sand or clay. With some few exceptions, all the true binders are bitumens, either natural or artificial.

TARS, THEIR MANUFACTURE AND PROPERTIES.

Coal Tars.—Coal is by far the most important source of tar. (a) Tar from Coke Ovens is made as follows: The coal is charged into long narrow hampers or retorts of about 4 or 5 tons capacity and heated by means of fires set in the retort walls; volatile matter held in the coal passes out through an opening in the top and is conducted through a series of washers and scrubbers, as in gas manufacture, to remove the tar and ammonia; the purified gas is then allowed to pass into a holder from which it is drawn as needed for burning under the retorts. (b) Tar from Gas Plants is unavoidable in the manufacture of illuminating gas; the bituminous coal is laced in fire-clay retorts about 8 ft. long, 15" high and 18" wide; 6 or 8 retorts set together in a furnace and forming a "bench;" a number of these benches built together is called a "stack;" the retorts are heated by means of a coke fire or by generator gas. The tar which collects in the hydraulic main, the condensers, and the tar towers, is run into large wells where it is allowed to settle; the accompanying ammoniacal liquor, being lighter than the tar, rises and is drawn off; the crude oil tar which remains is a black acid fluid with peculiar odor, and with specific gravity from 1.1 to 1.2. It presents about 5% of weight of coal. The true tarry products are artificial bitumens; the natural bitumens being found in various mineral oils and phalts. The nature and value of tar vary with the coal used, and with the temperature and other conditions under which it is produced. Free carbon, having no binding value, will prove detrimental. (c) Refined Coal Tar is obtained by fractional distillation for the separation of certain constituents used in the arts; the residue left in the still is known as coal-tar pitch, and is a thick viscous material while hot. It represents the true binding base of the tar, and if the tar is produced at comparatively low temperature the residue composed mainly of bitumens. After cooling for a few hours it is run out of the still and is graded as soft, medium or hard, according to its condition when cold. The dead oils, or heavier distillation products, and of less value than the other volatile distillates, are often run back into the still before the pitch is drawn off, in which case the pitch is liquid when cold. In preparing a tar for dust prevention, most of the valuable products are removed by fractionation, and the least valuable—as some of the carbolic and all the dead oils—are run back into the pitch until it reaches about the consistency of a heavy crude tar, sometimes adding dead oils from previous distillation, if necessary. These oils give life to the tar, and if percentage of pitch is not reduced too low the mixture has certain advantages over the crude tar, and it is comparatively free from naphthalin and anthracene and contains none of the volatile oils and ammoniacal liquor found in the latter. Dehydrated Tar (crude) is sometimes prepared for dust prevention, the aim being to remove all water, ammonium compounds, and some of the lighter oils. The absence of water makes it easier to handle when applied hot, and probably allows of a better absorption of the tar by the road surface. Water in tar hastens disintegration of the heavy binding materials; the ammoniacal liquor may saponify some of the oily products, mix with the water and wash out. Dehydrated tar may be prepared by boiling the crude material in open kettles until its boiling point lies between 105° and 110° C.

* Digest of Bulletin No. 34, Office of Public Roads, U. S. Dept. of Agric.,
 Wm. Hubbard, Assistant Chemist.

Water-Gas Tar has been used to some extent as a dust layer and road preservative. It is first obtained by admitting steam into a chamber called a generator which contains coke heated to incandescence; the water vapor reacts with this coke to form certain products and the mixture of gases is led into another chamber called the carburetor, where it meets a spray of hot oil, which is thus volatilized and carried to another chamber known as the superheater, where most of the hydrocarbons combine to form a permanent gas. The gas thus produced is washed with water and passed through extractors and scrubbers in much the same manner as ordinary coal gas, in order to remove the tarry products. The product is entirely different from ordinary coal-tar and contains a relatively small amount of heavy bitumens; the base is more or less thin, and of poorer binding quality than that of good coal tar; it may be used to advantage in certain instances, being cheap and easily handled. It compares quite favorably with the lighter oils, and oil and tar emulsions.

Composition of Tars.—The following Table shows some of the properties of crude coal tar, refined coal tar and water-gas tar, previously described. The notes to the table refer to the condition of distillates and residues when cold:

SPECIFIC GRAVITY AND COMPOSITION OF TAR PRODUCTS.

Kind of Tar.	Specific Gravity.	Ammoniacal Water.	Total Light Oils to 170°C.	Total Dead Oils 170°-270°C.	Residue (by difference).
		<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Water-gas tar. . . .	1.041	2.4	a21.6	b52.0	c24.0
Crude coal tar. . . .	1.210	2.0	d17.2	e26.0	f54.8
Refined coal tar. . .	1.177	0.0	b12.8	g47.6	j39.6

a Distillate mostly liquid.

b Distillate all liquid.

c Pitch very brittle.

d Distillate mostly solid.

e Distillate one-half solid.

f Pitch hard and brittle.

g Distillate one-third solid.

THE APPLICATION OF TARS.

Application to finished road surfaces.—The primitive method in this country is: Road surface first thoroughly swept to remove all dust; hot tar then spread on and thoroughly broomed in; road then, if possible, closed to traffic 12 hours to allow tar to soak in; at end of that time, or sooner, a coat of clean sand or stone chips applied to absorb excess of tar, and surface then rolled several times to bring it to proper condition quickly. The tar is heated in an open kettle preferably mounted on wheels and fitted with a portable fire-box. It is usually brought to its boiling point—about 190° F. (If temperature of crude tar is raised above 190° F. when heated it is very likely to foam up, boil over and catch fire.)—before being spread upon the road, although a lower temperature is sometimes sufficient; and if the kettle is of the above type the tar may be run out upon the road by means of a hose, the kettle being kept just in advance of the work; two kettles will allow continuous working, one being charged and heated while the other is in use; kettles to hold easily 9 barrels or about 450 gallons. Application of tar by mechanical means is also being used, notably in England.

Use of tar in road construction.—When a New Road is under construction, or an old road being resurfaced, the road should first be shaped and consolidated as well as possible without the use of water. The voids should be filled well with clean, fine stone chips free from dust, but an excessive amount of rolling should be avoided because if the roller is used too freely the larger stones will become rounded and covered with dust, thus preventing the tar from adhering properly. Hot tar may be applied to all the courses if desired, but sometimes only the upper course is so treated. After the tar has been applied, a dressing of fine material is spread on and the whole road well rolled. The tar may be spread by hand, but it is most economical to use a tar spreader: the spraying apparatus is mounted on wheels and is so arranged that the tar is forced from the tank in which it is heated, into an air receiver under a pressure of 150 to 350 lbs. per sq. in.; the necessary power

for pumping the air and the liquid into the receiver being obtained by means of chain drive from the road wheel. From the receiver the tar is distributed upon the road by means of specially designed spraying nozzles.

Amount and cost of materials.—According to conditions and methods of application, a surface-treated road will require from 0.35 to 0.70 gallons of tar per sq. yd. when applied by hand; and as small as 0.21 gallon has been used with good results when applied by machine, for first treatment. With either method the application of tar must be repeated from time to time, though less is required at each successive application. If tar is applied as road is built, as much as 1.5 gallons per sq. yd. are often consumed if spread by hand; but by means of devices like the pneumatic tar sprayers, it is claimed that the road stones to a depth of 3½" may be well covered with about 0.6 gallon per sq. yd. Crude coal tar can ordinarily be purchased from gas or coke companies at from 3 to 5 cts. per gallon; refined tars run from 6 to 12 cts. and even higher. The cost of treatment in France, by machine, will average about 3 cts., and by hand 5 cts.; in this country, where it is generally applied by hand, the cost ranges from about 6 to 12 cts. or more per sq. yd.

OILS, THEIR CLASSIFICATION AND PROPERTIES.

Oil fields.—There are seven distinct oil fields in the United States: 1st the Appalachian (including New York, Penn., W. Va., southeastern Ohio, and parts of Ky. and Tenn.) produces oils known as eastern oils or paraffin petroleum, and which are therefore of use only as temporary binders in dust suppression; 2nd the Ohio-Indiana field produces oils much like those of the Appalachian and are also classed as paraffin oils; 3rd the Colorado field, similar to above; 4th the Wyoming field with oils varying from the lighter oils, to the heavy asphaltic oils which are found principally in California; 5th the California field produces oils of the most varied character, consisting mainly of more or less dense asphaltic hydrocarbons, none of the components being of the paraffin series, the percentage of asphaltic residue usually high and of good binding character, the oils being considered the best for use as permanent binders; 6th the Texas field contains oils of a mixed character, with some paraffin as well as a greater or less amount of asphaltic residue, some having been used successfully as dust preventives, with others unfit for this purpose; 7th the Kansas field (including Oklahoma) produces oils quite similar to those from Texas. The same is true of Louisiana. In general, the eastern oils are of the paraffin type and useless as permanent binders; the western oils are of asphaltic character and of great value as permanent binders; while the southern oils are of a mixed character, their value as dust preventives lying in the relative amount of asphalt base contained.

Refining.—Although crude oil is used to a great extent in the West as a dust preventive, it is often customary in the East to partially distill oils containing asphaltic residues before using them, thus recovering many of the more valuable constituents and producing residual oils having a much better binding quality because they contain a larger percentage of asphalt base. Crude petroleum is an oily liquid, of unpleasant odor, with specific gravity from 0.73 to 0.97, according to locality from which it is derived; color from greenish brown to nearly black, often reddish brown or orange when viewed by transmitted light; sometimes fluorescent. The crude petroleum is refined by means of fractional distillation, somewhat similar to that for crude coal oil. The most valuable products are the kerosene, or burning oils, and the method called "cracking" is employed to increase their yield; this consists in modifying the fire, during process of distillation, so that only the bottom of the still is intensely heated, while top and sides, being exposed to the air, become somewhat cooled; thus the heavy oil vapors are condensed within the still itself, and upon dropping back into the residuum, which is much hotter than their boiling point, break up into lighter oils with lower boiling points, with a separation at the same time of free carbon or coke, which is deposited in the residuum. The paraffin petroleum residuums contain a large amount of paraffin hydrocarbons and paraffin scale or crude paraffin, and are unsuitable for road surface treatment. The base held by the California petroleum is composed of bitumens resembling asphalt; the residuum contains no paraffin and, if cracking has not been employed in its preparation, carries but little free carbon; both the crude oil and the residuums, if properly prepared, are excellent binders and give the best results of any oils which have been used as dust preventives. The semi-asphaltic oils, as from Texas, carry an asphaltic base, but also a considerable amount of paraffin hydrocarbons and

1% or more of paraffin scale; are somewhat inferior to the California products but often give good results.

Comparisons of crude oils and residuums.—The two following Tables show some results obtained from an examination of various crude and refined petroleum in the New York Testing Laboratory.

RESULTS OF TESTS OF CRUDE PETROLEUMS.

Kind of Oil.	Spec. Grav.	Flash- ing Point.	Volatil'y at 110°C. 7 hours.	Volatil'y at 160°C. 7 hours.	Volatil'y at 205°C. 7 hours.	Residue.

THE APPLICATION OF THE HEAVIER OILS.

To macadam surfaces.—Holes and inequalities should be repaired; not necessary to remove all dust as in case of tar, but sticks, leaves, etc., should be removed; crude oil either hot or cold, according to its viscosity and ability to penetrate the road surface; much cheaper applied cold. A covering of sharp sand or $\frac{1}{4}$ " stone screenings should be applied after the oil has been allowed to penetrate as much as possible, in order to take up all excess, and the surface well compacted by rolling, additional sand or screenings being thrown on wherever the oil shows a tendency to force its way to the surface and produce a sticky condition. Sometimes 2 or 3 courses of oil and screenings are applied.

During construction of macadam road.—The greatest success has been in California where the heaviest asphaltic oils are found; and the residuums obtained from the partial distillation of these oils have, so far, given the best results. The treatment is essentially the same as with tar, above described. The macadam is built in the usual manner and each course thoroughly rolled until the whole road is consolidated. A road constructed in this manner will require from $\frac{1}{4}$ to $1\frac{1}{2}$ gallons of oil per sq. yd.

To gravel roads.—A gravel road is oiled in much the same way whether it is an old road or one under construction, as only the upper course is treated in either case. Good drainage is very essential. The oil may be applied either hot or cold, according to its viscosity, by any method previously described. Where the treated surface is loose and contains a considerable amount of clay, the oil may be worked into the upper course by raking, insuring an equal distribution. After application of oil, the road should be rolled until properly compacted, adding fresh material as the oil works to the surface. Condensed specifications from biennial report (1906) by Commissioner of Department of Highways of California are: Sub-grade to be thoroughly rolled; then 2 layers of gravel, bottom layer 5" and top layer 3" after being rolled; 1st layer containing not larger than $2\frac{1}{2}$ " stone; gravel to

be evenly spread, well moistened, rammed 1 ft. from gutter or curb, and remaining portion rolled; depressions filled, moistened, and again rolled to unyielding surface; on this surface place the top layer of gravel, no stones over 1" diameter, and compacted in same manner. Oil should then be evenly distributed over the entire surface, $\frac{1}{2}$ gallon per sq. yd., and covered with clean, sharp sand until no oil can be seen; after 12 hours, another application of oil and sand in same manner, and rolled to unyielding surface. Use crude oil applied at temperature between 150° and 190° F.

To earth roads.—(a) The oil is simply sprinkled on the road, laying the dust and incidentally hardening the surface. Alkali soils disintegrate the oil and destroy its binding qualities. A sandy loam is the most suitable for treatment, usually giving good results when properly treated with an oil of good binding quality. Clay is probably the worst of all, as it does not absorb the oil well and exhibits a tendency to ball up and give trouble; sand should therefore be added to the clayey surface. Special attention should be paid to drainage, the roadbed to be dry when the oil is applied. (b) Another method: The road is first plowed to depth of 6" and properly crowned; all clods and lumps broken up by means of a harrow, and roadway well sprinkled with water; a specially constructed rolling tamper is then used by which the lower portion of the loose earth is compacted to depth of about 2", except in cases where sub-grade is unusually firm. After the lower portion is made firm, a heavy asphaltic oil is applied, 1½ gallons per sq. yd., and a cultivator passed over the road until the oil and earth are thoroughly mixed. The tamper is then used again, and the road is further compacted until only 1½" of loose material remain on top. Oil is again applied, and surface rolled with the tamper until firm, and finally it is ironed down with an ordinary roller, additional applications of earth being made wherever necessary to take up any excess of oil. A road constructed in this manner will require from 2½ to 3 gallons of oil per sq. yd. It is hard and dustless and resembles asphalt. California oils are the best. Texas and Kentucky oils cost from 4 to 8 cts. per gallon. The residuums and special preparations vary from 2 to 12 cts.

SPECIFICATIONS FOR COAL TAR.

I. When used as temporary binder it is usually employed in form of an emulsion; specifications difficult.

II. When used as a semi-permanent binder it is necessary that sufficient binding base be present to last through dusty season; and for economy, material to be sufficiently fluid to apply cold; hence—

1. Coal tar to be formed at low temperature, such as produced from by-product coke ovens or by gas plants.

2. A crude tar may be employed because of cheapness.

3. If not sufficiently fluid to apply cold, enough water-gas tar may be added to bring it to proper consistency, but proportion of latter should not exceed 50% of mix.

III. When used as a permanent binder for surface application, either a crude or a refined product may be employed, preferably the latter.

1. If a crude tar, it should have the following properties:

(a) Same as II, 1.

(b) Its specific gravity to be between 1.15 and 1.19.

(c) It should be free from water-gas tar and oil tar.

2. If a refined tar, the following might be specified:

(a) Same as II, 1.

(b) Its specific gravity to be between 1.17 and 1.20.

(c) No water nor ammoniacal liquor to be present; boiling point above 110° C. (230° F.).

(d) Upon distillation, at least 40% by volume of pitch should remain after all oils have been driven off below 270° C. (518° F.).

IV. When used as a permanent binder in road construction it is necessary that more binding base be present than is usually found in the crude

product. A refined product should therefore be employed; either prepared from a crude tar by the contractor or a special preparation purchased.

1. In the former case, a mixture may be prepared as follows from a crude tar, which meets the specifications set forth in III, 1:

- (a) The tar should be heated until boiling point is raised to at least 110° C. (230° F.).
- (b) One-tenth part or more of good soft pitch should then be dissolved in the tar while hot; the quantity added should be sufficient to produce a pitch residue of at least 50% by volume after all oils have been driven off under 270° C. (518° F.).

2. A refined tar for this purpose should meet the requirements as suggested for III, 2, except that the pitch remaining after volatile oils under 270° C. have been driven off should amount to at least 50% by volume.

In some cases, especially where climate is warm throughout the year, a tar considerably thicker in pitch may be preferred.

SPECIFICATIONS FOR MINERAL OILS.

(a) The oil shall have a specific gravity of not less than 0.95. (b) Its flash point shall not be lower than 300° F. (c) It shall be free from water as determined by the gasoline test. (d) When heated to 400° F. its loss in weight should not be over 35%. The character of the residue should be smooth and nearly solid when cold, but not so hard that it may not be easily dented with the finger, and when soft it should pull to a long, thin thread. (e) The oil shall be soluble in carbon disulphide to the extent of 98%, and in 88° naphtha to at least 88%.

EXPERIMENTS WITH DUST PREVENTIVES.

Note.—Following is from circular No. 89, Office of Public Roads, U. S. Dept. of Agric., issued April 20, 1908. During the past few years a number of preparations for laying and preventing dust have appeared on the market in competition with crude materials, such as coal tar and petroleum, and it was therefore decided by the Office of Public Roads to carry on a series of experiments during the summer of 1907 with a view to determining, if possible, the relative value of these preparations and crude products and their adaptability to different conditions. Experiments were conducted at Wayland, Mass., Washington, D. C., and Bowling Green, Ky. Following are results:

Experiments at Wayland, Mass.—The water-gas tar was obtained from a local gas company at \$1.50 per barrel of 50 gallons, delivered. The crude coal tar, in 50-gal. bbls. at \$2 per bbl., del. It had been produced at a low temperature and contained a good pitch base. The special coal-tar product was supplied free in 50-gal. bbls., the Office paying the freight from Boston to Wayland. It contained no water, was free from the extremely volatile oils present in the crude tar, and held a good pitch base. The other properties are shown in comparison with the water-gas and coal tars in preceding Table. Labor cost per 8-hour day was as follows: Common labor, \$1.50 to \$1.85; single teams, \$3; double teams, \$5; foreman, \$3; steam roller, \$12. The cost of repairs per sq. yd. of road surface was from 2.6 to 3.3 cts. When gravel was used it was obtained from pits near the road, costing the commission \$1.08 per cu. yd. Clean trap screenings, 1½", or pea stone, however, was used whenever it could be obtained and was furnished at \$1.10 per ton by a rock-crushing plant located about 4 miles from nearest section of work. Thirteen experiments were made as summarized in the two following Tables.

COST DATA OF TAR EXPERIMENTS.

Experiment No.	Material Supplied.	Cost of repairs per square yard.		Cost of application per square yard.			Cost of removing waste material per square yard.	Total cost per square yard.	Total cost of entire area.

Experiments at Washington, D. C.—With calcium chloride, as a dust preventive; tested on portion of macadam driveway in Agricultural Dept. grounds, Washington, D. C. The roadway is built of trap rock, held in position by a soft limestone binder; the screenings of the binder pulverized rapidly under traffic, forming a light dust continually raised by passing vehicles, and carried away by the wind; the road was thus becoming stripped of its binding material. In preparing for treatment, all dust and dirt were scraped from surface of roadway; a solution was prepared by mixing 300 lbs. of commercial calcium chloride (granular, containing 75% calcium chloride and 25% moisture) with 300 gallons of water in an ordinary street sprinkler, agitating the liquid thoroughly before applying. It was then applied from one sprinkling head, and the sprinkler passed slowly back and forth over the road to facilitate the complete absorption of the solution; each application consisting of 600 gallons over an area of 1582 sq. yds., or 0.38 gallon per sq. yd. The first application was made July 13, 1907, followed by a similar one July 15, to increase the efficacy of the treatment. The effect was marked. The texture of the road surface was completely changed: before treatment, raveling was excessive in spots and the whole surface seemed loosely knit together; after treatment of July 15, this condition changed and the road surface became smooth, compact and resilient. The third treatment, August 3rd, was given because certain points exposed to the most severe wear were showing signs of raveling; the results of this treatment, and of successive ones, were most satisfactory and not unlike those attending the first two treatments. The calcium chloride is charged at rate of \$16 per ton, f. o. b. cars at Baltimore; freight 13 cts. per 100 lbs. Specific gravity of solutions, 1.053 to 1.060. Following is Table of cost of applying:

COST OF APPLYING CALCIUM CHLORIDE.

Item.	Cost.
600 pounds calcium chloride, at \$18.60 per ton.....	\$5.58
3 men for 1½ hours, at 15 cents per hour.....	.675
1-horse sprinkling wagon for 1½ hours, at 35 cents per hour.....	.525
Total cost of 1,582 square yards.....	6.78
Cost per square yard at this rate.....	.0043
Total cost of five applications.....	33.90
Cost per square yard of five applications.....	.0215

Experiments at Bowling Green, Ky.—Materials used were Kentucky rock asphalt tested for its fitness as a binder in macadam construction, crude Kentucky oil, and special preparation of residuum oils, the last two of which were used as dust preventives.

(a) *Rock Asphalt Experiment.*—The rock asphalt used is a natural product formed in the Chester group of subcarboniferous rocks over a course extending through Breckenridge, Grayson, Edmonson, Logan, and Warren counties, marking the edge of the coal fields lying in the western part of Kentucky. It is a fine-grained sandstone impregnated with mineral pitch or bitumen, the latter averaging from 6 to 8%, with a maximum of 12%. After quarrying and crushing, 2" size, it is further passed between steel rollers, the finished product being a mass of individual grains of sand, each thoroughly coated with a film of mineral pitch, adhering to surrounding grains and packing very firmly if subjected to pressure; with a rich dark brown color with a slight luster which gradually disappears as the bitumen hardens and dries. If chilled when compacted, a lump becomes very hard and tough; if warmed in the hand, the bitumen becomes soft and semi-fluid and the individual grains of sand fall from the mass of their own weight. The test was made on Cemetery pike, a main thoroughfare. The form of construction originally adopted was a 20-ft. Telford road. When the surface had been worn away exposing the foundation, it was repaired and brought to grade with a sharp gravel containing about 20% sand and clay, the layer being about 8" thick when compacted. Previous to the experiment, it was loosened to a depth of 4" by means of a spiked roller and a heavy harrow, and shoveled out by hand. The sub-grade was then made to conform to crown of roadway, planned to be 4½" in 9 ft., or an average of ½" per ft. After rolling the sub-grade the wearing course of stone was laid; it consisted of crushed limestone.

1" to 1½", spread in a 4" layer, rolled once to turn down the sharp edges of the stone and form a smooth, even surface. The rock asphalt was then thrown on with shovels and spread to a depth of 1½", care being taken to break all lumps and to work all the asphalt rock possible into the interstices of the stone without disturbing the latter. As the work progressed, the roller was kept moving back and forth parallel to axis of roadway, working from outer edge to crown as in ordinary macadam construction. The inadvisability of working the material when chilled and damp was apparent, for the portion of the road laid at a temperature of 65° F. failed to become hard and firm for several hours after subsequent applications had compacted satisfactorily. The cost of the work is shown in the following Table. Labor ranged from \$1.20 to \$1.25, and teams cost \$3 per day of 10 hours; roller was loaned, cost of operation being \$2.50 per day for engineer plus cost of fuel; stone was delivered on roadway at \$1.20 per cu. yd. and was spread 4" thick uncompacted, making cost per sq. yd. delivered 13 cts; cost of asphalt charged at market price of \$5 per ton f. o. b. cars at Bowling Green; it was spread about 1½" thick, or at rate of 24.5 sq. yds. per ton.

Total.....	47.63	366.79	100.0

(b) *Oils*.—In connection with work on rock asphalt, experiments were made to determine the comparative value of a residuum oil preparation and kerosene oil, as dust preventives. The oil preparation is a patented mixture of residuum oils, combined with a view to obtaining such proportions of asphaltic and lighter oils as shall be best fitted for immediate dust laying and permanent improvement of the roadway. The tests were made on Cemetery Ave. beyond the point where the rock asphalt work ended. The general condition of the gravel roadway was unsatisfactory for the purposes of such test; the cross section of the roadway was quite flat, the crown having been completely worn down, so that lateral drainage was defective; also there were extensive pockets of loose material, characteristic of roads made of gravel containing a large percentage of sand and clay. Heavy rains had fallen for several days preceding the application of the oil, and although the road surface was quite dry there was a large amount of moisture in the road-bed, thus preventing the rapid absorption of the oil by the gravel before the evaporation of the lighter oils took place. The oils were applied over a width of 12 ft. of the roadway by means of an oil sprinkler adapted to the form spreading of heavy liquids. A tank load of the oil preparation was spread over an area of 841 sq. yds., or an average of 0.903 gallon per sq. yd.; the temperature of the oil 87° F. due to its exposure to the sun; it was heavy and was absorbed very slowly by the gravel, about 4 days being required to see it to become thoroughly incorporated into the surface of the road; the gravel becoming very compact and showing few traces of wheel marks except at points where repairs had been made, in which cases the cementing process took place more slowly. In the case of the crude oil, 5 tank wagons, a total of 3712 gallons, were applied to 4416 yards of surface, making an average of 0.84 gallon per sq. yd. An experiment was also made with crude oil on macadam road; there was about ¼" of dust on roadway consisting chiefly of powdered limestone; the roadway was given an application of 1000 gallons over an area of 1452 sq. yds., or at rate of 0.52 gallon per sq. yd. The following Table gives a statement of the cost of repairs, materials, and application of the oils.

			Anthracite coal.
			Succinite (amber).
Resinous.....			Copalite.
			Amberite, etc.
Cereous.....			Ozocerite.
			Hatchettite, etc.
Crystalline.....			Pichtelite.
			Hartite, etc.

TABLE II.—GROUPING OF NATURAL AND ARTIFICIAL BITUMINOUS COMPOUNDS.

Natural..	{	Mixed with limestone (asphaltic limestone).....	Seyssel, Val de Travers, Lobsan, Illinois, Utah, etc.
			California, Kentucky, Utah, etc.
			Trinidad, Cuba, California, Utah.
			Canada, California, Kentucky, Virginia, etc.
			Thick oils from distilled petroleum, "residuum."
Artificial.	{	Viscous.....	Gas tar.
			Pitch.
			Refined Trinidad asphaltic earth.
			Mastic of asphaltite.
			Gritted asphaltic mastic.
	{	Solid.....	Paving compounds.

The Adjustment of Macadam Road Design to Various Subgrade Soils (Report of Mass. Highway Commission; Eng. News, Sept. 4, 1902).—Deals with Sand and Gravel, Clay, and Sandy Loam.

Paving a Country Road With Brick (By Sam. Houston. Paper, Soc. C. E. & Surv., Jan. 20, 1902; Eng. News, Sept. 25, 1902).—Illustrates details in cross-section. Specifications and discussion under the following headings: Underdrains; Foundation of Broken Vitrified Pipe; Clay Curbing; Crown of Pavement and Curve of Summer Road; Pavement. Cost data is given showing that 5479 ft. of road cost \$7.72; the total width of road between ditches is 26 ft., with 10 ft. of pavement proper; etc.

An Experimental Steel Trackway in N. Y. City (Eng. News, Dec. 4, 1902).—Illustrated cross-section of trackway, and details of rail section, used in Murray St. Rails are special channel section, 40 ft. long, and weigh 25 lbs. per lin. ft. Approximate cost of trackway, laid, complete, \$7,500 per mile.

The Design of a Bituminous Macadam Road for Salem Co., N. J. (Eng. News, Sept. 24, 1903).—Illustrated cross-section of 30-ft. road.

Data on Roads and Pavements in Iowa (By A. Marston. Report, Iowa Eng. Soc.; Eng. News, Feb. 9, 1905).—Table of traction tests on brick and asphalt pavements in various stages of condition. Traction resistance: Brick pavement, 25.4 to 58 lbs. per ton. Asphalt pavement, 23.3 to 67.8 lbs. per ton.

Experience With Various Pavements on Streets With Heavy Grades (By C. G. Anderson. Paper, Ill. Soc. of Engrs. and Surv., Jan., 1907; Eng. News, Mar. 14, 1907).—Illustrated cross-sections showing different styles of paving employed.

Bituminized Dirt Roads at Santa Monica, Cal. (Eng. News, May 16, 1907).—Illustration of latest type of road-tamping roller.

Street Railway Track and Paving at Fort Wayne, Ind. (Eng. News, June 20, 1907).—Illustrations of track and paved streets, nose block for street railway track, and reinforced concrete poles.

Notes on Tar Macadam (By C. F. Wike, England; Eng. News, Aug. 8, 1907).—Initial cost of tar macadam roads in England is about 55 to 60 cents per sq. yd., exclusive of foundation; and the annual charge (including initial cost) for a period of 14 years has averaged 8 cents per sq. yd.—down to 5 cents.

The Use of T-Rails for Street Railway Tracks in Cities (By C. G. Reel, Paper, Am. St. & Int. Ry. Assn., Oct., 1907; Eng. News, Oct. 31, 1907).—Illustrations: Standard T-rail construction in Milwaukee; latest construction in Kingston, N. Y., showing special brick outside of rail.

Cost of Brick Pavements and Cement Mortar Curbs at Centerville, Iowa (By M. G. Hall. Eng. News, April 2, 1908).—Tables of costs.

Cost of Oiling Roads in N. Y. State (Eng. News, May 14, 1908).—Table showing costs of experimental road oiling, for macadam road, sand road, and gravel road.

Concrete Paving for Streets (Eng. News, Aug. 20, 1908).—Costs, and illustrated sections of Streets. Specifications.

Specifications and Notes on Macadam Road Construction (By A. N. Johnson. Paper, West. Soc. of Engrs., Oct., 1908; Eng. News, Nov. 5, 1908).

The Use of Asphaltic Flux for Coating Macadam Roads at Palo Alto, Cal. (By J. F. Byxbee. Eng. News, May, 13, 1909).—Specification and description of method. Total cost for material and labor, 8½ cents per sq. yd.

An "Accelerated Test" of Road Wear by Automobile Traffic in Germany (Eng. News, July 8, 1909).—Illustrated.

Method of Keeping Data Relating to Street Lines and Grades, in Brookline, Mass. (By H. A. Varney. Eng. News, July 8, 1909).—Illustrated sample pages of data sheets.

Sampittic Surfacing (By W. W. Crosby. Trans. A. S. C. E., Vol. LXIV., Sept. 1909).—Specifications.

Inverted Macadam Road Construction (Eng. Rec., Jan. 8, 1910).—Inverted macadam road construction has been adopted in a number of cases by Mr. A. N. Johnson, highway engineer of Illinois, as a means of meeting conditions which obtain in many parts of the State. The specifications proposed to cover this method of construction and the reasons for placing the fine material on the bottom and the large pieces of stone at the top were described in a paper Mr. Johnson presented before the Western Soc. of Engrs. This paper was printed in the Eng. Rec. of Nov. 7, 1908.

Vitrified Clay Curbing for Streets and Roads (Eng. News, Jan. 13, 1910).—Illustrated. The blocks are hollow and form continuous drains, so that the usual line of broken stone for drainage of the roadbed is not required where this form of curb is used. Has been used for eight years on the country

road between Toledo and Calumet, O., and is said to be in excellent condition, showing practically no wear.

Sidewalk Practice in Chicago (By N. E. Murray. Paper III. Soc. Engrs. and Survrs., Jan. 26, 28, 1910; Eng. News, Feb. 17, 1910).—The average cost of cement walks laid in Chicago from 1901 to 1908, inclusive, based on the total cost (\$8,918,278) divided by the total mileage (1862) was \$4,787 per mile, or 15.11 cents per sq. ft. This price was for walks complete, including filling, which in many instances was from 2 ft. to 6 ft. in depth and is not a fair average cost for the ordinary cement walk. Average Chicago prices for labor and material, give following average cost of material delivered on the work: Cinders, 50 cts. per cu. yd.; cement, \$1.20 per bbl. (3.8 cu. ft.); sand, \$1.75 per cu. yd.; gravel, \$1.50 per cu. yd. An ordinary concrete sidewalk gang in Chicago is usually composed of six men paid as follows (for 8 hours): 1 finisher at 65 cts., \$5.20; 1 helper at 47½ cts., \$3.80; 4 laborers at 37½ cts., \$12; total, \$21. Assuming that this gang of six men can construct 600 square feet of walk per day (a fair assumption, borne out by experience), we have, as total cost, 13.51 cents per sq. ft.; thus:—

Cinders (20% shrinkage), 20.83 cu. yds. at 50 cts.....		\$10.42
Base, 4½ ins. (1:2½:5):		
Cement, 9.77 bbls. at \$1.20.....	\$11.72	
Sand, 3.47 cu. yds. at \$1.75.....	6.07	
Gravel, 6.85 cu. yds. at \$1.50.....	10.28	28.07
Wearing coat, ½-in. (2:3):		
Cement, 5.56 bbls. at \$1.20.....	6.67	
Sand, 1.17 cu. yds. at \$1.75.....	2.04	8.71
Water, 1 mill per sq. ft.....		.60
Labor, 1 gang one day.....		21.00
Use of tools, waste of material, etc., at 2%.....		1.37
Sup't. and office expenses, at 5%.....		3.51
Profit at 10%.....		7.36
Total 600 sq. ft. at 13.51 cts. per sq. ft.....		\$81.04

Paving Practice in Chicago (By P. E. Green. Trans. A. S. C. E., Vol. XVI., Mar. 1910).—Crown of roadway: Chicago ordinance calls for arc of xvl, but the parabola is mostly used in construction; the formula is $y = \frac{x^2}{2a}$, in which b = depth of gutter below grade of center of roadway, a = half roadway, x = hor. dist. from center of roadway, and y = vert. dist. below the grade. Above formula applies to roadways up to 100 ft. and to pavements having a rigid wearing surface; for wider roadways, and with acadam surfaces, the curve should approach a straight line from center of roadway to gutters. The Rosewater (Omaha) formula for height of crown $H = W(100 - 4P) + 5000$, in which H = height of crown, W = width of roadway, and P = percentage of grade; this formula is best adapted to park roads or boulevards, or for streets having stiff grades where little crown is necessary. For residence streets a good formula is $H = 0.02W$. Illustrations of girder rail and pavement.

Two Years' Experience in Dust Suppression on New Jersey Roads (By James Owen. Paper before State Sanitary Assn., of N. J.; Eng. Rec., Dec. 1910).—Mr. Owen records some of his failures in road construction, and draws certain conclusions as the results of his experience: "In construction, no penetration of heavy oil, but construct the road as of ordinary macadam and provide after complete consolidation of surface a coating of 45% using about one-half gallon per sq. yd., and in the maintenance contract the year provide for two applications in that period. With this practice the satisfaction has been realized." It is apparent that an ordinary acadam surface, even when oiled, is not satisfactory, but satisfaction has been obtained with various patent pavements as Amiesite, Filbertine, Greenite and what is known as road asphalt. These all use the broken stone with a plastic mixture injected, in most cases asphalt. Cost.—Before automobile era, the cost of maintaining a good surface upon the Essex county roads was 3 cts. per sq. yd. per annum. This was increased in later years to about 5 cts., and including the oiling, amounts to 6 cts. The present pavements alluded to cost from 80 cts. to \$1.20 per sq. yd. It is obvious that those pavements must last 15 to 20 years to be on the same sanitary basis as ordinary repairs.

Tests of Various Road Surfacing Materials by the Ohio State Highway Department (Bulletin No. 12, O. S. H. D.; Eng. News, Nov. 10, 1910).—The following table shows the wear on Nelson Avenue experimental road, one year after its construction:

Section.	8 ft. East.	4 ft. East.	Center line.	4 ft. West.	8 ft. West.
1. Glutin.....	.07 ft.	.07 ft.	.00 ft.	.00 ft.	.00 ft.
2. Standard Asphalt.....	.02 ft.	.07 ft.	.06 ft.	.08 ft.	.09 ft.
3. Pioneer Asphalt.....	.07 ft.	.07 ft.	.05 ft.	.03 ft.	.03 ft.
4. Tarvia "X".....	.02 ft.	.04 ft.	.04 ft.	.05 ft.	.03 ft.
5. Tarvia "B".....	.08 ft.	.04 ft.	.03 ft.	.00 ft.	.00 ft.
6. Indian Asphalt.....	.01 ft.	.03 ft.	.01 ft.	.03 ft.	.02 ft.
7. Ugite.....	.04 ft.	.05 ft.	.05 ft.	.03 ft.	.05 ft.
8. Fairfield Asphalt.....	.04 ft.	.04 ft.	.04 ft.	.05 ft.	.00 ft.
9. Asphaltilene.....	.05 ft.	.04 ft.	.04 ft.	.05 ft.	.03 ft.
10. Rock Asphalt.....	.00 ft.	.00 ft.	.02 ft.	.03 ft.	.04 ft.
11. Carbo-Via.....	.03 ft.	.09 ft.	.07 ft.	.08 ft.	.07 ft.
12. Concrete Macadam.....	.04 ft.	.05 ft.	.05 ft.	.01 ft.	.00 ft.
13. Taroid.....	.02 ft.	.01 ft.	.03 ft.	.00 ft.	.00 ft.
14. Petrolithic.....	.03 ft.	.01 ft.	.06 ft.	.00 ft.	.00 ft.
15. Limestone Concrete.....	.04 ft.	.06 ft.	.02 ft.	.00 ft.	.00 ft.
16. Gravel Concrete.....	.00 ft.	.00 ft.	.00 ft.	.00 ft.	.01 ft.
17. Water-bound Macadam.....	.01 ft.	.03 ft.	.03 ft.	.01 ft.	.01 ft.

61.—HYDROSTATICS.

Hydrostatics, in its broadest sense, treats of the conditions of equilibrium and pressure of fluids* at rest. As the term "fluid" comprehends both liquids and gases our discussion will be confined to the former, and especially to water. To the engineer, Water may be considered as practically *frictionless* and *incompressible*. In other words, we assume it to be a perfect fluid possessing no statical friction; and not subject to increased density under pressure, to any perceptible degree.† From this it follows (1) that the intensity of pressure (in lbs. per sq. in., or lbs. per sq. ft.) at any given point in the liquid is equal in all directions; (2) that, neglecting the weight of the atmosphere above, the intensity of pressure is directly proportional to the depth below the surface; (3) that the intensity of pressure is directly proportional to the density (= mass of a unit of volume) or to the weight, of a unit volume of the liquid; (4) that the pressure is always normal to any plane, pressed surface; (5) that the pressure on a curved surface may be resolved into one or more resultant pressures each acting normal to a tangent plane projected on the curved portion.

The reader is referred to the subject of Dams, pages 845, etc., for many of the elementary principles of hydrostatics which bear particularly on that subject, and they will not be repeated here.

Atmospheric Pressure may be neglected in most hydrostatic calculations because its effects are usually balanced. For instance, the effect of the atmospheric pressure on the up-stream water surface at a dam exerts so much additional force tending to overturn the structure, but it must be remembered that an equal and opposite pressure is exerted against the down-stream face of the dam, tending to preserve equilibrium, and hence the effect is neutralized‡. The height of the atmosphere above sea level is variously estimated at from 40 to 200 miles. Whatever the height may be, it is certain that, beginning with the maximum density at sea level, it becomes exceedingly rarefied above an elevation of 30 to 40 miles. A column of air at sea level will balance a column of water 34 ft. in height or a column of mercury 2½ ft. (30 ins.) in height, each column exerting a pressure of 14.7 lbs. per sq. in. This is based on a cubic ft. of water weighing about 62.5 lbs., and the specific gravity of mercury at 13.6.

Air, dry, at atmospheric pressure, and at a temperature of 56° F., weighs exactly 1/16 of a pound per cubic foot. (See Table of weight of air, page 463.)

Water is 773 times as heavy as the denser air at 0° C. A column of water 33 ft. in section and 1 ft. high weighs about 0.434 lb.; or, in other words, 1 ft. "head" corresponds to a "pressure" of about 0.434 lb. per sq. in. Hence a pressure of 1 lb. per sq. in. corresponds to a head of about 2.304 ft. These values should be committed to memory.|| Table No. 1, following, when used decimally will give corresponding pressures in lbs. per sq. in. for any given heads in ft., and *vice versa*.

* "*Incompressible*" fluids, only, are included in the modern acceptation of the term *hydrostatics*.

† Under one atmosphere (14.7 lbs. per sq. in.) fresh water is compressed 0.99995 its original volume, amounting to an increased density of 0.0032 per cu. ft.; salt water to 0.999956 its original volume. Sea water one ft. in depth below the surface, equal to 156 additional atmospheres or 2 lbs. per sq. in., is compressed only to 0.99995566 its original volume; hence the additional 156 atmospheres increases its density only about 1/4 of 1% more than does one atmosphere.

‡ This is only partly true, as a partial vacuum is frequently formed at the up-stream face when the water is *flowing over* the crest of the dam.

|| The refinement sometimes employed by using about 62.424 to 62.428 as the weight of a cu. ft. of water at its maximum density, is unnecessary in ordinary engineering problems. The value 62.5, used above, involves an error of only 0.5 lb. pressure per sq. in. for a 1000-ft. head, equivalent to 1/10 of 1 per cent on the side of safety. But see Tables 3, 4 and 5, *wing*.

Hydrostatic Pressure.—There are two *Pressure Units* in general use in the United States, as follows:

- (a) "Lbs. per sq. in." corresponding to head in ft., as given in Tables 1, 3 and 4, is used in the design of water pipes, tanks, sewers, etc.
 (b) "Lbs. per sq. ft." corresponding to head in ft., is used in the design of dams. See Tables 2 and 5.

Let P = total pressure in lbs. on any submerged plane surface;

p' = pressure in lbs. per sq. ft.;

p'' = pressure in lbs. per sq. in.;

h = height of column of water or "head," in ft.;

a' = area of submerged surface acted upon, in ft.;

a'' = area of submerged surface acted upon, in ins.;

w' = wt. of a column of water 1 ft. high and 1 ft. sq., in lbs. = 62.5 lbs.;

w'' = wt. of a column of water 1 ft. high and 1 in. sq., in lbs. = .434 lb.

Then, neglecting atmospheric pressure (14.7 lbs. per sq. in.), we have,

$$P = w' a' h = 62.5 a' h \quad \dots \dots \dots (1)$$

$$= w'' a'' h = .434 a'' h \quad \dots \dots \dots (2)$$

$$p' = w' h = 62.5 h \quad \dots \dots \dots (3)$$

$$p'' = w'' h = .434 h \quad \dots \dots \dots (4)$$

$$h = \frac{p'}{w'} = .016 p' \quad \dots \dots \dots (5)$$

$$= \frac{p''}{w''} = 2.304 p'' \quad \dots \dots \dots (6)$$

1.—HEAD AND PRESSURE EQUIVALENTS.—LB. PER SQ. IN.

(Water assumed at 62.5 lbs. per cu. ft.)

Head. Feet.	Pressure. Lbs. per Sq. In.	Pressure. Lbs. per Sq. In.	Head. Feet.
1	0.434	1	2.304
2	0.868	2	4.608
3	1.302	3	6.912
4	1.736	4	9.216
5	2.170	5	11.520
6	2.604	6	13.824
7	3.038	7	16.128
8	3.472	8	18.432
9	3.906	9	20.736
10	4.340	10	23.040

Example.—What pressure in lbs. per sq. in. corresponds to a head of 104.8 ft.?

Solution.— $100 = 43.4$
 (From above $4 = 1.736$
 table.) $.8 = .347$

Ans. 45.488 lbs.

2.—HEAD AND PRESSURE EQUIVALENTS.—LBS. PER SQ. FT.

(Water assumed at 62.5 lbs. per cu. ft.)

Head. Feet.	Pressure. Lbs. per Sq. Ft.	Pressure. Lbs. per Sq. Ft.	Head. Feet.
1	62.5	1	.016
2	125.	2	.032
3	187.5	3	.048
4	250.	4	.064
5	312.5	5	.080
6	375.	6	.096
7	437.5	7	.112
8	500.	8	.128
9	562.5	9	.144
10	625.	10	.160

Example.—Pressure corresponding to 82.4 ft. head = $5000 + 125 + 25 = 5150$ lbs. per sq. ft. Or, $= 62.5 \times 82.4 (= .9^\circ \times 82.4)$, by formula.

Example.—Head corresponding to pressure of 1250 lbs. per sq. ft. = $16 + 3.2 + .8 = 20$ ft. Or, $= .016 \times 1250$, by formula.

3.—HEAD OF WATER, IN FEET

Corresponding to

GIVEN PRESSURES IN LBS. PER SQ. IN.

Note.—Weight of water assumed at 62.424 lbs. per cu. ft.

Initial point may be moved simultaneously to right or left for Pressure and Head.

Example.—A pressure of 45.3 lbs. per sq. in. is equivalent to (moving the initial point one place to left in 453 and 1044.98) 104.5 ft. head.

4.—PRESSURES IN LBS. PER SQ. IN.

Corresponding to

GIVEN HEADS OF WATER, IN FEET.

Note.—Weight of water assumed at 62.424 lbs. per cu. ft.

Decimal point may be moved simultaneously to right or left for Head and Pressure.

[Pressure in Lbs. per Sq. In.]

At a depth of 344 ft. below the surface, the pressure is 21473.80 lbs. per sq. ft.

At a depth of 34.4 ft. below the surface, the pressure is 2147.380 lbs. per sq. ft.

The Center of Pressure on any submerged plane surface is the point of resultant pressure on that surface. We have explained, under Dams, page 846, the position of the center of pressure on rectangular surfaces. We will now present a general formula for finding the center of pressure on any plane surface, and whether vertical or inclined.

Let $t b$, Fig. 1, represent the edge of a submerged plane figure of any shape (as a rectangle, circle, triangle, etc.);

α , the angle which this plane makes with the water surface;

D_x , the inclined distance (ft.) from A to the center of gravity, or to the horizontal neutral axis, of the figure $t b$;

D_0 , the inclined distance to the center of pressure;

h_x , the head in feet on the center of gravity;

h_0 , the head in feet on the center of pressure;

a' , the area in sq. ft. of the surface $t b$. Also—

Let I_x —the moment of inertia of the figure $t b$ about a horizontal neutral axis passing through its center of gravity;

I_A —the moment of inertia of the figure $t b$ about a horizontal axis passing through A ,

$$= I_x + a' D_x^2;$$

S —the statical moment about A ,

$$= a' D_x;$$

$$\text{Then } D_0 = \frac{I_A}{S} = \frac{I_x + a' D_x^2}{a' D_x} \dots \dots \dots (7)$$

$$\text{And } h_0 = D_0 \sin \alpha = \frac{I_x + a' D_x^2}{a' D_x} \sin \alpha \dots \dots \dots (8)$$

Having obtained h_0 we can easily find the total pressure P from formulas (1) and (8); thus, making $h = h_0$,

$$P = 62.5 a' h = 62.5 a' h_0 = 62.5 \left(\frac{I_x + a' D_x^2}{D_x} \right) \sin \alpha \dots \dots \dots (9)$$

If the submerged figure $t b$ is rigid, the pressure P may be considered as a resultant pressure acting normal to the surface $t b$ at the center of pressure distant h_0 ft. vertically (or D_0 ft. inclined) below the surface of the water. Moreover, if the figure $t b$ is vertical, $\alpha = 90^\circ$ and $\sin \alpha = 1$ in equations (8) and (9); hence, $h_0 = D_0$.

The practical application of equations (8) and (9) consists in substituting the proper values for I_x , a' , D_x and $\sin \alpha$ in the second members of the equations. The angle α , the distance $A t$, and the shape and dimensions of the figure $t b$ will usually be given; then find I_x and $D_x - A t$, from the tables in Section 29, page 524, etc.

Problem.—Let $t b$ represent the section of a triangular plane of altitude $t b = 12$ ft. and horizontal base at bottom $b = 8$ ft. Let it be submerged so that $A t = 10$ ft., and $\alpha = 60^\circ$. Find the head h_0 on the center of pressure? Find the total pressure P ?

Solution.—From Table 6, next page, we deduce $I_x = 8 \times \frac{(12)^3}{36} = 384$, and $D_x = 10 + \frac{1}{3} \times 12 = 18$. Area of triangle $a' = 12 \times 4 = 48$; $\sin \alpha = 0.866$. Then, (8), $h_0 = \frac{384 + 48 \times 324}{48 \times 18} \times 0.866 = 18\frac{1}{3} \times 0.866 = 15.973$ ft.; and $P = 62.5 \times 48 \times 15.973 = 47,919$ lbs. Ans.

Any other shaped figure may be treated in the same manner. The center of pressure will always be found *below* the center of gravity of the figure.

If the figure $t b$ is a rectangle, in a vertical plane, and with the top t at A , just touching the surface of the water, then $D_0 = h_0 = \frac{1}{3} t b$ (Fig. 1).

The position of the center of pressure is essential in designing large hydraulic gates, valves, etc.

a'	= Area.	$b_1 d$	$\frac{b_1 d}{2}$	$\frac{\pi d^2}{4}$	$\frac{\pi d^2}{2}$
h_z	= distance to neutral axis.	$h_1 + \frac{d}{2}$	$h_1 + \frac{d}{3}$	$h_1 + \frac{d}{2}$	$h_1 + \frac{4d}{3\pi}$
I_A	About axis at water surface.	$a' \left(h_1^2 + h_1 d + \frac{d^2}{3} \right)$	$\frac{b_1 d^3}{12} + b_1 d h_1 \left(\frac{h_1}{2} + \frac{d}{3} \right)$	$\frac{5\pi d^4}{64} + \frac{\pi d^2 h_1}{4} \left(h_1 + d \right)$	$\pi d^2 \left(\frac{d^2}{4} + h_1^2 \right) + \frac{4d^3 h_1}{3}$
h_0	= $\frac{I_z + a' h_z^2}{a' h_z}$.	$I_A + \left[b_1 d \left(h_1 + \frac{d}{2} \right) \right]$	$I_A + \left[\frac{b_1 d}{2} \left(h_1 + \frac{d}{3} \right) \right]$	$I_A + \left[\frac{\pi d^2}{4} \left(h_1 + \frac{d}{2} \right) \right]$	$I_A + \left[\frac{\pi d^2}{2} \left(h_1 + \frac{4d}{3\pi} \right) \right]$
y_0	= neutral axis to center of pressure.	$h_0 - \left(h_1 + \frac{d}{2} \right)$	$h_0 - \left(h_1 + \frac{d}{3} \right)$	$h_0 - \left(h_1 + \frac{d}{2} \right)$	$h_0 - \left(h_1 + \frac{4d}{3\pi} \right)$

And when the tops of the orifices touch the surface of the water, h_1 becomes zero and we have, in each case, the following values:
(b) Special Cases—Surface of water at tops of orifices.

h_z	= distance to neutral axis.	$\frac{d}{2}$	$\frac{d'}{3}$	$\frac{d}{2}$	$\frac{4d}{3\pi} = 0.424 d$
I_A	= $I_z + a' h_z^2$.	$\frac{b_1 d^3}{3}$	$\frac{b_1 d^3}{12}$	$\frac{5\pi d^4}{64}$	$\frac{\pi d^4}{8}$
h_0	= $\frac{I_A}{a' h_z}$.	$\frac{2d}{3}$	$\frac{d}{2}$	$\frac{5d}{8}$	$\frac{3\pi d}{16} = 0.589 d$
y_0	= $h_0 - h_z$.	$\frac{d}{6}$	$\frac{d}{6}$	$\frac{d}{8}$	$0.165 d$

Pressure in Pipes, Tanks, etc.—In Fig. 2, let h be the total head in ft. at any level, on each diameter d of sections A , B , and C . A is a water pipe leading from the water tank B , which in turn is connected by the tube t with the tank C through the vertical tube T . Then it follows that the water surfaces in B and T must remain at the same level. From formulas (3) and (4) we have for either section A , B or C , at a depth h below the surface:

Pressure in lbs. per sq. ft. = $62.5 h$;

Pressure in lbs. per sq. in. = $.434 h$.

If d' = the diameter in feet, and d'' = the diameter in inches, then A , B and C will each have to resist a bursting pressure of $62.5 h d'$ lbs. per lin. ft., or $.434 h d''$ lbs. per lin. in. of pipe or tank; and *each side* would have to resist *one-half* that pressure.

The combination of the tube T inserted in the tank C (with t omitted) illustrates what is called the "hydrostatic paradox." The *unit* pressure at d due to the head h remains the same no matter what the diameter of T . Clearly, the diameter of T does not affect the unit pressure; the height h does. Thus, a heavy cask, as C , may be made to burst if even a small tube, as T , is filled with water so as to give the required bursting head.

Flotation.—The weight of a substance is proportional to its density; and the relative density of a substance, referred to water, is called its *specific gravity*.^{*} Hence, of two substances of equal weight, that one having the least volume has the greater specific gravity. As the volume of a body is affected by heat, it follows that the specific gravity of substances decreases with a rise in temperature, the formation of ice being a phenomenal exception to this law. Pure water at 4° C. its maximum density, is assumed to have a specific gravity of 1; and all other substances, at 0° C. are referred to that standard. A porous substance will increase in density by absorbing water; thus, water-soaked logs is an instance of this kind.

Any solid with specific gravity greater than unity will sink; if less than unity it will float. Any floating body, whether solid or not, will displace a volume of water whose weight is equal to the weight of the body; if the body sinks, the weight of the volume of water displaced will be less than that of the body.

The Depth of Flotation depends upon the specific gravity of the body, if solid; upon the *average* specific gravity of the volume, if hollow; and upon

Fig. 3.

the surface form of the body. Assuming the average specific gravity of volume to be less than unity, let d = depth of flotation,

s = average specific gravity of volume of body;

then for any rod, bar, tube, cylinder, etc., of uniform cross-section and of length l , floating vertically,

$$d = sl \dots \dots \dots (10)$$

For the same, if lying horizontal, d can be obtained by fixing the water surface on the end section at such elevation (Fig. 3) that

$$s = \frac{\text{shaded area below water surface}}{\text{total area of the section}} \dots \dots \dots (11)$$

Buoyancy.—Let Figs. 4, 5 and 6 represent oval sections, and Fig. 7 a circular section, of any body floating in water, with the surface at S ; then—

Stable equilibrium is represented by Fig. 4,

Unstable equilibrium, by Fig. 6;

Neutral equilibrium, by Fig. 7.

^{*} For discussion of Specific Gravity, see page 460, etc.

The position in Fig. 5 can obtain only when some *outside force* is applied, as will be seen from the following discussion: The center of buoyancy B in each figure below is the center of gravity of the displaced water; and G is the

Fig. 4.

Fig. 5.

Fig. 6.

Fig. 7.

center of gravity of the body. Then, as long as G and B are in the same vertical line there is some kind of equilibrium, as stable, unstable, or neutral, because the resultant downward weight of the body, acting in a vertical line passing through its center of gravity G , must be equal and opposite to the resultant upward pressure R of the water below the body. Furthermore, the upward resultant pressure R will not be changed in position, direction or amount if we imagine the body to be removed from the "depression" in the water and that depression refilled with the displaced water; for equilibrium would be maintained by the equal weight of the displaced water, its resultant passing vertically through its center of gravity B . Hence if R , acting vertically, is equal and opposite to the resultant weight of the body and also to the displaced water, acting through their respective centers of gravity G and B , then it follows that G and B are in the same vertical line when the body is in equilibrium.

The equilibrium of a floating body may be tested by noting the position of the "metacenter" M when the body is slightly disturbed in any direction from a position of rest. (M is the intersection of the "equilibrium axis" $a-a$ with a vertical through B .)

- (a) When M rises above G it indicates that the body was in stable equilibrium.
- (b) When M falls below G it indicates that the body was in unstable equilibrium.
- (c) When M coincides with G it indicates neutral equilibrium.

In the above, Fig. 5 shows that Fig. 4 is in stable equilibrium. In the same way it can be proved that Fig. 6 is unstable, and Fig. 7 neutral.

The following rules apply not only to floating bodies but to supported bodies in general.

- 1) A body is in stable equilibrium when a slight change tends to raise its center of gravity;
- 2) A body is in unstable equilibrium when a slight change tends to lower its center of gravity;
- 3) A body is in neutral equilibrium when a slight change neither raises nor lowers its center of gravity.

62.—HYDRAULICS.

Hydraulics embraces the application of the principles of both hydrostatics and hydrokinetics;* for a fluid at rest, as treated by hydrostatics, is but the lower limit of a condition of motion. It therefore treats of the laws governing the pressure, flow and energy of water (and other liquids) with the accompanying phenomena. These laws, however, are but imperfectly understood and, like all other branches of engineering, hydraulics is not an exact science. *Theoretical* hydraulics assumes no loss of energy during the flow, a condition which can never obtain in practice; but its great value, in the investigation of any problem, lies in fixing the upper limit of efficiency which can ever be expected. *Practical* hydraulics is founded on theoretical hydraulics, but takes into consideration the losses of energy during the flow. These losses are deduced from experiments.

Theory of Flow.—Under *hydrostatics* we have discussed the relation between the static head h and the pressure p of still water. In hydraulic computations it is convenient to reduce all pressures, velocities and losses of every description to equivalent heads and losses of head. Moreover, the unit of pressure used is, in English units, the "lb. per sq. in." Thus, referring particularly to a pipe line, we have:

- p = pressure in lbs. per sq. in. = $0.434 h_p$;
- H = hydrostatic head, or simply static head = $2.304 p$;
- h_e = entry head, or loss of head at entry;
- h_v = velocity head, or head due to velocity at given section;
- h_a = "velocity of approach" head, or gain in head a given section due to velocity of approach above the given section;
- h_f = friction head, or loss of head due to friction;
- h_s = "suction" head, or head due to suction, acting in the direction of the flow;
- h_c = "curvature" head, or loss of head due to curves or bends;
- h_p = pressure head, or head due to the resultant pressure at a given section (i. e., piezometer head);
- h_x = "expansion head," or loss of head due to expansion of section;
- h_c = "contraction head," or loss of head due to contraction of section;
- h_t = total loss of head above a given section.

Then, using the same sub-notation for the velocity, we have, by theory:
 V = theoretic velocity due to H , or $V^2 = 2gH$; $v_a^2 = 2g h_a$;
 $v_e^2 = 2g h_e$; $v_f^2 = 2g h_f$; $v_c^2 = 2g h_c$; $v_x^2 = 2g h_x$;
 $v_s^2 = 2g h_s$; $v_p^2 = 2g h_p$; $v_t^2 = 2g h_t$;
 $v^2 = 2g h_v$; in which the gravity acceleration $g = 32.16$, and $\sqrt{2g}$ = say 8.02.

Considering the gains and losses in the pipe line, the following relations exist:

Gains				Losses				
Pres.	Stat.	Appr.	Suct.	Veloc.	Entry	Fric.	Curv.	Expan. Contr.
h_p	$= H$	$+ h_e$	$+ h_s$	$- h$	$- (h_e + h_f + h_c + h_x + h_t) \dots (1)$			
$\frac{v_e^2}{2g}$	$= \frac{V^2}{2g}$	$+ \frac{v_a^2}{2g}$	$+ \frac{v_s^2}{2g}$	$- \frac{v^2}{2g}$	$- \left(\frac{v_e^2}{2g} + \frac{v_f^2}{2g} + \frac{v_c^2}{2g} + \frac{v_x^2}{2g} + \frac{v_t^2}{2g} \right) \dots (2)$			

If we neglect the velocity of approach and the suction head, and let h represent the losses in head (mostly friction), equations (1) and (2) reduce to

$$h_p = H - h - h_t \dots \dots \dots (3)$$

$$\frac{v_e^2}{2g} = \frac{V^2}{2g} - \frac{v^2}{2g} - \frac{v_t^2}{2g} \dots \dots \dots (4)$$

Combining (3) and (4), we have the general equation (5), following.

* The term hydrodynamics was formerly defined as the science which treats of the motion of liquids (now included under hydrokinetics), but it now has a broader acceptation: The science which treats of the laws of force as applied to fluids. Hence it comprises hydrostatics and hydrokinetics.

locity and Discharge.—The velocity of discharge v at any section is obtained from equation (1), by substituting $\frac{v^2}{2g}$ for h , and trans- as follows:

$$v = \sqrt{2g(H - h_p - h_1)} \dots \dots \dots (5)$$

ressure head h_p equals zero for any given section, and we also assume as h_1 , then

$$v = \sqrt{2gH} = 8.02\sqrt{H} \dots \dots \dots (6)$$

following is a table of theoretic velocities for various heads, calcu- om equation (6). See, also, table on page 283.

The theoretic velocity, therefore, is the same as that which would be acquired by the water (or any other body) falling freely in vacuo through the height H . Also, from equation (6), we have

$$H = .01555 v^2 \dots \dots \dots (7)$$

The Discharge through a pipe, when the velocity is known, is obtained from the following simple formula:

$$q = a v \dots \dots \dots (8)$$

In which q = discharge in cu. ft. per *sec.;

a = area of cross-section of flowing water, in sq. ft.;

v = mean velocity of flow, in ft. per sec.

Then, from (8) and (5) we have, for any practical case,

$$q = 8.02 a \sqrt{H - h - h_1} \dots \dots \dots (9)$$

which takes into consideration all the losses of head. If there are no losses in head, and no pressure head at the section considered, then we have for the theoretical discharge, since, $h_p = 0$, $h_1 = 0$,

$$q = 8.02 a \sqrt{H} \dots \dots \dots (10)$$

in which $8.02 \sqrt{H}$ is the theoretic velocity (equation 6) whose values are given in Table 1, preceding.

†Table 2, following, gives the areas of pipes in square feet for various diameters in feet and inches:

Problem 1.—What is the least diameter of pipe that could possibly be used for discharging 300 cubic ft. per sec. under a 14-ft. head?

Solution.—Neglecting friction and other losses we have from Table 1, page 1155, that the theoretic velocity is 30 ft. per second. Without the use of any formula† we know that the area of pipe required = $\frac{300}{30} = 10$ sq. ft.:

and, from Table 2, page 1157, the corresponding diameter is 3 ft. 6½ ins. Hence, we know that the diameter would have to be larger than 3 ft. 6½ ins. to take care of the friction- and other losses.

In practice, after a pipe has been properly designed to meet the conditions of the problem and take care of all losses of head, it is customary to increase the diameter of the pipe somewhat: (1) to provide for future increased demands on the supply, and (2) to anticipate the roughening of the inner surface of the pipes from rust or vegetable growth. Sewer pipes are increased usually about 2 ins. in dia.; water mains, about the same; and small pipes, 10 to 50% in area.

* To find cubic feet per minute,	multiply q by	60
“ “ “ hour,	“ “	3,600
“ “ “ 24 hours,	“ “	86,400
“ “ “ 30 days,	“ “	2,592,000
“ “ “ 365 days,	“ “	31,536,000

To reduce cubic feet to gallons, multiply by $\frac{1728}{231} = \frac{576}{7 \times 11} = 7.48052$

† See, also, tables of circles, pages 230-235.

‡ Or, from equation (5), $q = a v$, we have $a = \frac{q}{v} = \frac{300}{30}$.

Note.—Areas of pipes are proportional to the squares of their diameters.

Example.—The area of pipe 2' 6" in dia. = 4.909 sq. ft. Then, for a pipe 0" dia., $a = 4.909 \times 4$; for 7' 6" dia., $a = 4.909 \times 9$; for 10' 0" dia., $a = 4.909 \times 16$; etc. See, also, Tables 13-15, pages 230-235.

Velocity inversely proportional to a and to d^2 .—When a pipe of variable cross-section is discharging a constant, full volume of water, as per Fig. 1, we have,

$$q = a v = a_1 v_1 = a_2 v_2 = a_3 v_3, \text{ etc.} \dots \dots \dots (11)$$

$$\text{But } a = \frac{\pi d^2}{4}; a_1 = \frac{\pi d_1^2}{4}; a_2 = \frac{\pi d_2^2}{4}; \text{ etc. Then } q = \frac{\pi d^2}{4} v = \frac{\pi d_1^2}{4} v_1 = \frac{\pi d_2^2}{4} v_2, \text{ etc.} \dots (12)$$

Fig. 1.

$$\text{Whence } v = \frac{q}{a}; v_1 = \frac{q}{a_1}; v_2 = \frac{q}{a_2}; \text{ etc.} \dots \dots \dots (13)$$

$$\text{Or, } v = \frac{4q}{\pi d^2}; v_1 = \frac{4q}{\pi d_1^2}; v_2 = \frac{4q}{\pi d_2^2}; \text{ etc.} \dots \dots \dots (14)$$

In which q = discharge in cubic feet per second;

d, d_1, d_2, d_3 = diameter of pipe in feet at different sections;

a, a_1, a_2, a_3 = area of pipe in sq. ft. at sections d, d_1, d_2, d_3 ;

v, v_1, v_2, v_3 = velocity of flow in ft. per sec. at sections a, a_1, a_2, a_3 ;

$$\pi = 3.1416;$$

$$\frac{\pi}{4} = 0.7854.$$

It is to be noted that the above formulas represent the practical relations which may exist in any pipe line regardless of friction and loss of head. These formulas may be transposed in various ways. If it is desired to substitute the "head" of water in place of the velocity we must be careful to use the velocity head h and not the static head H . Thus, from (6), (13) and (14) we have

$$q = \frac{\pi d^2}{4} \times 8.02 \sqrt{h} = 6.298908 d^2 \sqrt{h} \dots \dots \dots (15)$$

$$\text{whence } d = 2 \sqrt{\frac{q}{8.02 \pi \sqrt{h}}} = 0.3984 \frac{\sqrt{q}}{\sqrt[4]{h}} \dots \dots \dots (16)$$

and if all friction and other losses are neglected, $h = H$,

$$\text{and } d = 2 \sqrt{\frac{q}{8.02 \pi \sqrt{H}}} = 0.3984 \frac{\sqrt{q}}{\sqrt[4]{H}} \dots \dots \dots (17)$$

Hence it is seen that the diameter of the pipe is directly proportional to the square root of the discharge, and inversely proportional to the fourth root of the "head." Solving Problem 1 by equation (14), we obtain

$$d = 0.3984 \frac{\sqrt{300}}{\sqrt[4]{14}} = 3.57 \text{ ft.} = 3 \text{ ft. } 6\frac{1}{2} \text{ ins.}$$

We will now take up the question of "losses" of energy, head and pressure, which occur during flow.

Losses During Flow.—In the following discussion reference is made to Fig. 2, showing water discharging from the upper reservoir U. R., through the pipe line od , into the lower reservoir L. R.

o = orifice, intake or inlet end of pipe, at which a gate is placed;

d = discharge end, or outlet of pipe, at which a gate is placed;

V = Venturi water meter, inserted in the pipe line for measuring the discharge;

V = Venturi itself, or the contracted section of the meter;

t or c = contracted section of the pipe line;

T or e = expanded section of the pipe line;

b = bend in the pipe line.

During flow, loss of head will occur at all these points; and throughout the whole line, due (1) to the friction of the water along the sides of the pipe, and (2) to the lateral or radial forces* set up by the impingement of

* Usually termed *viscosity*.

the water particles against each other in oblique directions to the flow. But (1) and (2) are usually grouped together under the symbol h_f = loss of head due to friction (see page 1160).

There are two other losses of head which have to be considered, namely, (1) loss due to "dropping" head (decrease of H) in the upper reservoir, and (2) loss due to "rising" head, above d , in the lower reservoir (decrease of H_2); the static head H at d , is $H_2 + h'$ when the water surface in L. R. is below d ; and H_2 when above d .

Fig. 2.—Pipe Line Between Reservoirs.

Explanation of Figure 2.—A *hydraulic grade line* is a line of "no pressure." That is, if a vertical tube or piezometer is inserted in the top of a pipe line at any point it will be found that the water will rise in the piezometer tube to the hydraulic grade line and thus indicate the pressure head h_p at that point of the line. Hence, a H. G. L. is very useful in the study of any pipe line as it gives directly the pressure head at any point. The above Figure shows five H. G. L.'s, (a), (b), (c), (d) and (e), which will be explained:

(a).—This can obtain only when a gate is closed in the pipe line as at d , or some other point. As soon as the gate is opened, water will begin to discharge at d and the end of the H. G. L. at L will drop.

(b).—This condition will obtain with the gate at d , *partly open*, when the H. G. L. would drop to M and the pressure head h_p at d would equal $H_2 + h' - H_1$ if the surface of water in L. R. is below d ; or $H_2 - H_1$ if surface of water is above d . The total loss of head is $H_1 - h$, the latter being the velocity head. Note that the H. G. L. SM is straight only when the loss of head is uniform or proportional to the length of the line. The discharge at d will issue with a velocity $*v = 8.02 \sqrt{h}$, h forming a fractional part of H_1 .

(c).—This is the usual condition for a pipe line of *uniform cross-section* discharging freely, that is, all gates open, and the water-level below d in L. R. Note that there is no pressure head above the top of the pipe at d because the efflux does not quite fill the discharge end; but the actual *mean pressure head* at d is shown in Fig. 3, by h' , the depth below the free surface, and the velocity of discharge at outlet is $v = 8.02 \sqrt{h'}$ + velocity of approach.

Fig. 3.

(d).—The hydraulic grade line is here shown as a very broken or irregular line, and marks the elevation at which the water would rise in the piezometer tube if inserted in the pipe line at any point. The pipe is as shown in Fig. 2, and *not* uniform in section as was assumed with (b) and (c). A sharp drop (to the right) in the H. G. L. indicates a greater *rate* of loss of head, per lin. ft. of pipe, than one of flatter slope. Thus, the grade drops sharply, by comparison, at c and e , points of abrupt change in diameter; at f , the converging tube leading to the venturi V ; and at the bend b . The curved form of the H. G. L. at section A is due to a loss of head at the orifice o forming a downward (first) part of curve; while the upward (second) part of the curve is due to suction by vacuum just beyond the orifice. A similar suction occurs just beyond the venturi V causing an upward H. G. L. at section H . Note that the H. G. L. at section D is sharper than at sections F , I and K because the area of the pipe is less, therefore the velocity, friction and rate of loss of head are greater. The conditions at the outlet d

* Treated as a weir without end contraction; see Weirs, page 1177, etc.

are the same as described in (c). This case (d) represents a usual occurrence in practice, and the losses are described in detail in the following pages. It may be remarked here, however, that the pressure head h , at any point in the pipe line is the vertical distance from the H. G. L. to the center of pressure of the water section in the pipe. The center of pressure is usually assumed at the center of a circular pipe, although in reality it is a little below the center.

(e).—Here, it is assumed that the water in the lower reservoir has risen above the discharge end d of the pipe, to the elevation of s' . The theoretic head is therefore H_3 . Now we know that the total loss of head cannot exceed the theoretic head H_3 , therefore the H. G. L. must slope to some point x , above or at s' . Moreover, we know that x must be above s' , otherwise there would be no pressure head ($x s'$) to cause a flow into L. R. We can reasonably assume $x s'$ to be less than h' (say about half the diameter of the pipe) and to diminish as s' rises in elevation, so that when $H_3 = 0$, $x s' = 0$ also.

Total Head is usually sub-divided into *entry head*, *velocity head* and *friction head*. That is, the force exerted by the pressure due to the total head, as in a reservoir, is expended partly (1) in overcoming the resistance at the entrance of the pipe; (2) in producing velocity of flow or discharge; (3) in producing friction (and viscosity). There is a fourth resistance which has to be overcome, namely, *curvature head**, but this is usually included in an ordinary pipe line, under *friction head*. The combined entry and velocity heads seldom exceed one foot even when the entrance is sharp-edged, in which case they are about equal. The entry head reduces with increased length of pipe line, becoming inappreciable when the length exceeds about 1000 diameters. Even for short pipe lines, less than 1000 diameters, the entry head almost entirely disappears with the use of the bell-shaped or flaring entrance. It is thus seen that the main considerations in any ordinary pipe line are velocity head and friction head. Moreover, one is a function of the other so that, for a given smoothness of wetted surface and a given diameter of pipe, they both increase with the hydraulic slope. The relations between velocity head (or rather velocity due to the velocity head), friction head, smoothness of wetted surface, and hydraulic slope, constitute the laws of flow and when thoroughly known, may be incorporated in a working formula.

Loss of Head due to Friction.—In long pipe lines this is really the only loss that is practically considered, or at least other incidental losses are included in "friction" losses. The "dropping" head as in emptying a reservoir may be reduced to "mean average" head or, with more exactness to several mean average heads at successive elevations of water surface. The loss of head at entrance becomes almost a negligible quantity; moreover, the orifice is usually a converging tube, thereby reducing the loss to a minimum. Similarly, converging and diverging "reducers" are inserted in a line joining pipes of different diameters, thereby greatly reducing the loss of head which would obtain if the change were abrupt as at c and e , Fig. 2. Where such changes of section occur frequently, as in lap-jointed riveted steel pipe (Fig. 4), it is customary to use the smaller diameter d in computing the flow. The losses due to contraction of sections at c , and the expansion at e , together with the loss effect due to rivet heads are considerable, and it is a question whether a *uniform* pipe of diameter d would not show the greater capacity. The losses due to bends are seldom computed unless the curvature is considerable. Short curves, moderately sharp, are the best.

Friction losses are deduced from experiments on pipe lines actually constructed, and from laboratory experiments. The former point to a safe

Fig. 4.—Riveted Pipe.

* The loss of head due to curvature of pipe, as short curves, bends, etc., is but imperfectly understood. Theoretical formulas, as those of Weisbach, are not reliable. Roughly speaking, the loss of head in a short 90° bend may be assumed at 3 to 5 times what it would be in the same length of straight pipe. For a good discussion of this subject see Paper No. 911 in Trans. Am. Soc. C. E., for April, 1902, by Gardner S. Williams, Clarence W. Hubbell and George H. Fennell.

precedent for *similar* designs, while the latter lead to the establishing of general laws of flow, in a *relative* sense. It would hardly be safe, however, to design large pipe lines based on formulas derived from laboratory experiments alone. Many physicists have attempted to formulate laws of flow and of friction based almost wholly on theory without considering the viscosity of the flowing liquid. It is perhaps needless to say that all such formulas, while interesting, are practically useless to the engineer, and they are positively dangerous to the young student. The class of formulas which the hydraulic engineer is using to-day, and will continue to use, are founded on experimentation. Experiments reveal to us that—

- Friction F of water in pipes is proportional to some *variable power* of the velocity v , that is, $F \propto v^x$. In pipes of commercial size the values of x have been found to range from about $x = 1.75$ to $x = 2$, depending on the diameter of pipe and roughness of wetted surface, or perimeter.
- Friction is proportional to the length of the pipe, so far as at present known.
- Friction is less in curves of short radius, down to $2\frac{1}{2}$ diameters, than in curves of long radius, for the same total angle of deflection. (See Trans. Am. Soc. C. E., Vol. XLVII, pages 183, 191.)
- Friction is inversely proportional to some power of the diameter of the pipe or the hydraulic radius r of the conduit. The index of the power may be assumed as 1.2, within small limits of error.
- Friction increases rapidly with the roughness of the wetted perimeter. A newly laid conduit with a smooth surface can often deteriorate so that the velocity of discharge will decrease from 2 to 5 per cent per annum for a number of years.

Author's Hydraulic Formula.—The following general formula is based on the most reliable existing experimental data, and is applicable to the flow of water in pipes, sewers, flumes, etc.

Notation:

- a = area of cross-section of water in pipe, flume, etc., in sq. ft.;
 v = velocity of discharge in ft. per second ($v = \frac{q}{a}$);
 q = discharge in cubic ft. per second ($q = av$);
 H = loss of head in friction, etc., in ft. per 1000 ft. ($H = 1000 s$);
 s = hydraulic slope or sine of angle of slope ($s = .001 H$);
 p = wetted perimeter of cross-section of pipe, etc., in ft.;
 r = hydraulic (mean) radius in ft. $= \frac{a}{p}$. (For circular pipe $r = \frac{d}{4}$);
 d = diameter of circular pipe in ft. ($d = 4r$);
 c = coefficient of smoothness of wetted surface; also alinement;
 x = index of the power of the velocity, proportional to friction;
 y = index of the power of d or $4r$, inversely proportional to friction.

* As the velocity of discharge v increases with the mean radius r , it is desirable to design the section of the conduit so that r will be a maximum for the area a , other things equal. The circular section is ideal in this respect, and the value of r is equal to $\frac{d}{4}$ whether the circular pipe is full, as in Fig. 5, or only half full, as in Fig. 6. When not full, but more than half full, $r > \frac{d}{4}$; $r = 0.3043$ (its maximum value) when the depth of water in the circular pipe is $0.81d$. When the pipe is less than half full, $r < \frac{d}{4}$. Fig. 7 shows the

Fig. 5. Fig. 6.

Fig. 7.

Fig. 8.

section of a flume, in which r has its maximum value when $b_1 = 2d_1$. Practical considerations however usually call for a less proportionate depth. Fig. 8 is a section of a trapezoidal canal in which r is a maximum when $b_1 = 2(x - y)$, or $b_1 = 2d_1 (\csc \theta - \cot \theta)$. In practice, canals and ditches are usually designed with such slopes as will probably be maintained without wash during the flow of water.

Formulas:

	Hyd. Radius, r .	Diameter, d .
General:	$H = \frac{1}{c} \cdot \frac{x^2 v^2}{(4r)^7}$	$H = \frac{1}{c} \cdot \frac{x^2 v^2}{d^7} \dots \dots \dots (1)$

But x generally varies from 1.75 to 2.00 — somewhat nearer the former value; and y varies usually from 1.15 to 1.25. Assuming average values of x and y , we have, $x=1.82$; $x^2=3.31$; $\frac{1}{x}=0.55$; $\frac{1}{x^2}=3.0$; $y=1.2$.

Hence, $H = \frac{1}{c} \cdot \frac{v^{1.82}}{3(4r)^{1.3}} \quad H = \frac{1}{c} \cdot \frac{v^{1.82}}{3d^{1.3}} \dots \dots \dots (2)$

Equation (2) is the author's formula for loss of head in feet per 1000 feet. The various values of c , v , r , d , and H , raised to the proper powers, are given in the subjoined Tables 3, 4, 5, 6 and 7. Other forms of (2) which are useful in practice are the following:

Hydraulic slope, $s = .001 H \dots \dots \dots (3)$

Velocity, $v = (3c)^{0.55} H^{0.55} (4r)^{0.66} = (3c)^{0.55} H^{0.55} d^{0.66} \dots \dots \dots (4)$

Diameter, $d = \frac{1}{(3c)^{0.55}} \cdot \frac{1}{H^{0.55}} \cdot v^{1.82} \dots \dots \dots (5)$

Hydraulic radius, $r = \frac{d}{4} \dots \dots \dots (6)$

*Coefficient, $c = \frac{v^{1.82}}{3H(4r)^{1.3}} = \frac{v^{1.82}}{3Hd^{1.3}} \dots \dots \dots (7)$

Note that H = hydraulic slope mult. by 1000.

* Formula (7) is used in determining the coefficient c of smoothness and alinement in pipe lines actually built and tested. The values given in Table 3 are close averages from actual experiments.

3.—VALUES OF COEFFICIENT *c* OF SMOOTHNESS AND ALINEMENT IN AUTHOR'S FORMULA, PRECEDING.

Class. (1)	Surface. (2)	Description of Material. (3)	Age. (4)	Alinement. (5)	$\frac{1}{c}$ (6)	<i>c</i> (7)	$c^{0.55}$ (8)	$(3c)^{0.55}$ (9)	$\frac{1}{(3c)^{0.55}}$ (10)
A	Extremely Smooth.	Smooth metals brass; lead. Well planed timber, pipe. Smooth cast iron, pipe.	New. "	Straight. "	1.00	1.00	1.00	1.83	0.40
B	Very Smooth.	Metals; brass; lead. Well planed timber, pipe. Cast iron pipe. Smooth steel pipe.	5 yrs. 3 yrs. New.	Few curves. " Straight.	1.10	.91	.95	1.74	0.43
C	Fair.	Wood-stave pipe (ordinary). Cast iron pipe. Smooth steel pipe.	7 yrs. 5 yrs. New.	Str. and curved. " Few curves.	1.20	.83	.90	1.66	0.47
D	Not Clean.	Cast iron pipe (ordinary). Riveted steel pipe. Neat cement. Vitrified brick.	10 yrs. 4 yrs. New. New.	Str. and curved. " " "	1.50	.67	.80	1.46	0.56
E	Unclean.	Cast iron pipe. Riveted steel pipe (ordinary). Brick; sewers.	20 yrs. 12 yrs. 10 yrs.	Str. and curved. " "	1.90	.53	.70	1.29	0.68
F	Rough.	Cast iron pipe. Riveted steel pipe. Rough brickwork.	30 yrs. 20 yrs.	Str. and curved. "	2.50	.40	.60	1.10	0.86
G	Very Rough.	Badly tuberculated pipe. Unclean sewers.			3.50	.29	.50	0.92	1.14

4.—VALUES OF $v^{1.82}$ FOR VARIOUS VALUES OF v
IN AUTHOR'S FORMULA, PRECEDING.

Ex.—For hydraulic slope $s = .004$, $H = 4.0$, $H^{0.55} = 2.144$, and $\frac{1}{H^{0.55}} = .315$.

Problems in Use of Author's Hydraulic Formula.

(See page 1161, etc.)

Problem 1.—What loss of head per 1000 ft. would occur in an ordinary iron pipe line 20 ins. in diameter, if the velocity is 3 ft. per second?

Solution.—Use formula (2); then $\frac{1}{c}$, from Table 3, = 1.50; $v^{1.48}$, from Table 4, = 7.39; $\frac{1}{d^{4.75}}$, from Table 6, = 0.542; hence, $H = 1.50 \times 7.39 \times \frac{1}{4} \times 0.542 = 2.00$ ft. per 1000 ft. *Ans.*

Problem 2.—What velocity of discharge would be expected in an unglazed, egg-shaped, brick sewer, whose hydraulic radius is 0.75, and hydraulic coefficient 0.00125?

Solution.—Use formula (4); then from the Tables, $(3c)^{0.55} = 1.29$; $1.25^{0.55} = 1.13$; $(4r)^{0.48} = d^{0.48} = 3^{0.48} = 2.065$; hence, $v = 1.29 \times 1.13 \times 2.07 = 2.92$ ft. per sec. *Ans.*

Problem 3.—What diameter of riveted-steel pipe would be required to discharge 2.4 cu. ft. per second, after it has been in use about 12 years, if hydraulic slope is 0.01225?

Solution.—Use formula (4) by trial method—assuming d , obtaining v , then $q (=av = 2.4)$. *First*, assume pipe to be 12 ins. in diameter; then 1. $v = 1.29 \times 3.97 \times 1 = 5.12$; $q = av = 0.7854 \times 5.04 = 4.02$; hence, as 4.02 is a 12-in. pipe is too large. *Second*, assume pipe to be 10 ins. in diameter; then $d = 0.833$; $v = 1.29 \times 3.97 \times 0.887 = 4.54$; $q = av = 0.5454 \times 4.54 = 2.48$, required discharge being 2.4; hence a 10-in. pipe is required. *Ans.*

Problem 4.—A conduit whose hydraulic radius is 0.875, and whose hydraulic slope is .001375 has a velocity of discharge of 4.5 ft. per second. What is the coefficient c of smoothness and alinement of the conduit?

Solution.—Use formula (7), in which $v = 4.5$, $H = 1.375$, and $4r = 3.5$; then by use of accompanying Tables, $c = \frac{15.45 \times 0.2224}{3 \times 1.375} = 0.83$, which places under Class C in Table 3.

Chezy's Hydraulic Formula assumes the velocity to be proportional to the square root of both the hydraulic radius and the hydraulic slope; or

$$v = c\sqrt{rs} \dots\dots\dots (1)$$

which c is a coefficient to be determined by experiment. (See Kutter's formula, following.)

Kutter's Formula, so-called, is really the Chezy formula (preceding), but the values of the coefficient c supplied so as to give it a general application. These values of c were deduced from experiments made by Ganguillet and Kutter, and were primarily intended to apply to the flow of water in streams and canals. They have, however, received general application, to a greater or less extent, in the design of water mains, sewers, flumes, ditches, etc. The value of the coefficient in English* measure is as follows:

$$c = \frac{\frac{1.811}{n} + 41.65 + \frac{.00281}{s}}{1 + \frac{n}{\sqrt{r}} \left(41.65 + \frac{.00281}{s} \right)} \dots\dots\dots (2)$$

which r and s are the mean radius and the slope, respectively, as explained

* In metric measure,

$$c = \frac{\frac{1}{n} + 23 + \frac{.00155}{s}}{1 + \frac{n}{\sqrt{r}} \left(23 + \frac{.00155}{s} \right)} \dots\dots\dots (3)$$

on page 1161; and n is a coefficient depending upon the roughness of the wetted surface of the conduit, sewer, canal, or stream. Thus,

$n = .009$ for well-planned timber, perfectly aligned.*

$n = .010$ for neat (pure) cement; glazed or enameled surfaces generally; smooth cast iron or iron pipes; planed timber.*

$n = .011$ for cement with one-third sand, in good condition; well-jointed pipes of iron†, cement, and terra cotta.

$n = .012$ for unplanned timber in good alinement, as flumes.

$n = .013$ for ashlar and brickwork, well laid; ordinary metal; earthen-, cement-, stoneware- and terra cotta pipe not well pointed nor in first-class order; cement plaster and planed timber in second-class condition; generally, the materials for $n = .010$ when imperfect in quality or condition.

$n = .015$ for unclean surfaces in pipes and sewers; second-class or rough brickwork; stonework, well dressed; iron-, stoneware- and terra cotta pipes with imperfect joints and in bad condition.

$n = .017$ for rubble masonry in good order; brickwork, stoneware and ashlar in poor condition; generally, the materials for $n = .013$ when imperfect in quality or condition; tuberculated iron pipes;

$n = .020$ for canals in very firm gravel, and carefully trimmed; inferior rubble in cement; coarse, dry rubble.

$n = .0225$ for coarse, dry rubble in bad condition.

$n = .025$ for canals and rivers free from stones and weeds, and in good order.

$n = .030$ for canals and rivers having some stones and weeds.

$n = .035$ for canals and rivers in bad order, with great quantities of stones and weeds.

$n = .040$ for rivers in extremely bad condition.

These values of n are to be inserted in equation (2) for finding the value of c used in equation (1). The correct use of Kutter's (or Chezy's) formula depends upon the proper selection of the values of n for the roughness of the wetted surface. The values $n = .010$ to $n = .016$ will cover all conditions for good water mains—the lower values for the smooth pipes, and the higher values for the pipes with rough surfaces. (See, also, page 1188.)

In order to simplify the calculations of the coefficients c in Kutter's formula, equations (1) and (2), the following reductions of form of equation (2) are given for various values of roughness n . It remains only to substitute the proper values of—

r , the hydraulic radius of the pipe, sewer or canal, in ft.;

d , the diameter of the circular pipe, in ft.;

s , the average slope of the pipe, or rate of fall of the hydraulic grade line.

$$\begin{array}{cc} \text{Using Hyd. Rad } r. & \text{Using Diameter } d. \\ \text{For } n = .009, c = \frac{\sqrt{r}(242.872s + .00281)}{s(\sqrt{r} + .37485) + .0000253} = \frac{\sqrt{d}(242.872s + .00281)}{s(\sqrt{d} + .7497) + .0000506} & (4) \end{array}$$

$$\text{For } n = .010, c = \frac{\sqrt{r}(222.75s + .00281)}{s(\sqrt{r} + .4165) + .0000281} = \frac{\sqrt{d}(222.75s + .00281)}{s(\sqrt{d} + .833) + .0000562} \quad (5)$$

$$\text{For } n = .0105, c = \frac{\sqrt{r}(214.13s + .00281)}{s(\sqrt{r} + .437325) + .0000295} = \frac{\sqrt{d}(214.13s + .00281)}{s(\sqrt{d} + .87465) + .000059} \quad (6)$$

$$\text{For } n = .011, c = \frac{\sqrt{r}(206.29s + .00281)}{s(\sqrt{r} + .45815) + .0000309} = \frac{\sqrt{d}(206.29s + .00281)}{s(\sqrt{d} + .9163) + .0000618} \quad (7)$$

* The values $n = .010$ and $n = .0105$ are often used for wood-stave pipe well laid, with dressed timber.

† The values $n = .014$ and $n = .016$ are often used for lap-jointed steel-riveted pipe. For foul and tuberculated iron pipe, use $n = .016+$.

Using Hyd. Rad r .Using Diameter d .

$$\text{For } n = .012, c = \frac{\sqrt{r}(192.57s + .00281)}{s(\sqrt{r} + .4998) + .0000337} = \frac{\sqrt{d}(192.57s + .00281)}{s(\sqrt{d} + .9996) + .0000674} \quad (8)$$

$$\text{For } n = .013, c = \frac{\sqrt{r}(180.96s + .00281)}{s(\sqrt{r} + .54145) + .0000365} = \frac{\sqrt{d}(180.96s + .00281)}{s(\sqrt{d} + 1.0629) + .0000730} \quad (9)$$

$$\text{For } n = .014, c = \frac{\sqrt{r}(171.01s + .00281)}{s(\sqrt{r} + .5831) + .0000393} = \frac{\sqrt{d}(171.01s + .00281)}{s(\sqrt{d} + 1.1662) + .0000786} \quad (10)$$

$$\text{For } n = .015, c = \frac{\sqrt{r}(162.38s + .00281)}{s(\sqrt{r} + .62475) + .0000422} = \frac{\sqrt{d}(162.38s + .00281)}{s(\sqrt{d} + 1.2495) + .0000844} \quad (11)$$

$$\text{For } n = .017, c = \frac{\sqrt{r}(148.18s + .00281)}{s(\sqrt{r} + .70805) + .0000478} = \frac{\sqrt{d}(148.18s + .00281)}{s(\sqrt{d} + 1.4161) + .0000956} \quad (12)$$

$$\text{For } n = .020, c = \frac{\sqrt{r}(132.20s + .00281)}{s(\sqrt{r} + .833) + .0000562} = \frac{\sqrt{d}(132.20s + .00281)}{s(\sqrt{d} + 1.666) + .0001124} \quad (13)$$

$$\text{For } n = .0225, c = \frac{\sqrt{r}(122.14s + .00281)}{s(\sqrt{r} + .93713) + .0000632} = \frac{\sqrt{d}(122.14s + .00281)}{s(\sqrt{d} + 1.87426) + .0001264} \quad (14)$$

$$\text{For } n = .025, c = \frac{\sqrt{r}(114.09s + .00281)}{s(\sqrt{r} + 1.04125) + .0000703} = \frac{\sqrt{d}(114.09s + .00281)}{s(\sqrt{d} + 2.0825) + .0001406} \quad (15)$$

$$\text{For } n = .030, c = \frac{\sqrt{r}(102.02s + .00281)}{s(\sqrt{r} + 1.2495) + .0000843} = \frac{\sqrt{d}(102.02s + .00281)}{s(\sqrt{d} + 2.499) + .0001686} \quad (16)$$

$$\text{For } n = .035, c = \frac{\sqrt{r}(93.39s + .00281)}{s(\sqrt{r} + 1.45775) + .0000984} = \frac{\sqrt{d}(93.39s + .00281)}{s(\sqrt{d} + 2.9155) + .0001968} \quad (17)$$

$$\text{For } n = .040, c = \frac{\sqrt{r}(86.925s + .00281)}{s(\sqrt{r} + 1.666) + .0001124} = \frac{\sqrt{d}(86.925s + .00281)}{s(\sqrt{d} + 3.332) + .0002248} \quad (18)$$

Coefficients c in Kutter's formula, for various values of roughness n , mean radius r , and slope s , are given in Table 8, following. Intermediate values of c , for values of n , r and s not given in the Table, may be obtained by interpolation, by simple proportion. In cases where the slope s is greater than $s = .01$, section 7, the values of c as deduced from section 7 may be considered sufficiently accurate—a little too large for values of r greater than 3.28 (1 meter), and a little too small for values of r less than 3.28. Note that the value of c is independent of the slope s in all cases where the mean radius $r = 3.28$ (1 meter); and for this reason the "one meter" line is shown in Italics in each of the 7 sections. Above the one-meter line the values of c increase with the slope s ; below, they decrease.

For explanation of the use of Kutter's formula and Table 8, see Practical Examples following the table.

PRACTICAL EXAMPLES IN USE OF KUTTER'S FORMULA AND TABLE 8.

(1) Given, the average or mean cross-section of a stream; to find the mean radius r ?

Calculate or scale the area a in sq. ft. of the section of flowing water; also, the wetted perimeter p in ft., or transverse length of (sectional) contact of flowing water with the stream bed. Then, $r = \frac{a}{p}$.

(2) Given, a stream, canal, or pipe line, etc., of average uniform section; to find the hydraulic slope s ?

s = the average fall in ft. of the stream or canal, per foot of length; or the fall in ft. of any hydraulic grade line, per ft. of length.

(3) Given, the character of a stream, canal, or pipe line; to find the roughness n ?

Consult the tabular values, page 1168.

(4) Given, the co-efficient c , mean radius r , and slope s ; to find the velocity v ?

From Chezy's formula, $v = c\sqrt{rs}$. Note that the roughness n is not considered directly because c and n are functions of each other; but as c is given, n can be obtained if desired. (The discharge in cu. ft. per sec. $= q = av$, in which a = the area of cross-section of the discharging volume, in sq. ft.)

(5) Given, roughness $n = .014$, mean radius $r = 18$, slope $s = .0003$; to find velocity v ?

First, find c from sections 4 and 5 of Table 8: $c = \frac{1}{1.2247 \times .02} (154.9 + 157.6 + 152.1 + 154.5) = 154.8$. Then $v = c\sqrt{rs} = 154.8 \times 4.243 \times .01732 = 11.38$ ft. per sec.

(6) Given, velocity $v = 1.2$ ft. per sec., mean radius $r = 1.5$, slope $s = .0004$; to find n ?

First find c , $= \frac{v}{\sqrt{rs}} = \frac{1.2}{1.2247 \times .02} = 49.0$. Then from section 5 of preceding Table, on line with $r = 1.5$, we find that a coefficient c of 49.7 corresponds to $n = .030$; $\therefore$ use $n = .030$.

(7) Given, roughness $n = .017$, slope $s = .001$, velocity $v = 2.2$ ft. per sec.; to find the mean radius r ?

Use "cut and try" method: assume r in the equation, $r = \frac{1}{s} \cdot \frac{v^2}{c^2} = 1000 \frac{v^2}{c^2}$. 1st, let $r = 1$, then from section 6 of Table 8, $\frac{1}{s} \cdot \frac{v^2}{c^2} = 1000 \times \frac{(2.2)^2}{(86)^2} = 0.65$; 2nd, let $r = 0.8$, then $\frac{1}{s} \cdot \frac{v^2}{c^2} = 1000 \times \frac{(2.2)^2}{(81.8)^2} = 0.72$; 3rd, let $r = 0.75$, then $\frac{1}{s} \cdot \frac{v^2}{c^2} = 1000 \times \frac{(2.2)^2}{(80.45)^2} = 0.75$. $\therefore r = 0.75$. Checking, $v = c\sqrt{rs} = 80.45 \times 0.866 \times 0.03162 = 2.2$, the given velocity.

(8) Given, mean radius $r = 6$, roughness $n = .020$, and required velocity $v = 3$; to find the slope s ?

Use "cut and try" method: assume s in the equation $s = \frac{1}{r} \cdot \frac{v^2}{c^2} = \frac{1}{6} \cdot \frac{v^2}{c^2}$. 1st, let $s = .0001$, then from section 6 of Table 8, $\frac{1}{r} \cdot \frac{v^2}{c^2} = \frac{1}{6} \cdot \frac{9}{(102.1)^2} = .000144$; 2nd, let $s = .00015$, then $\frac{1}{r} \cdot \frac{v^2}{c^2} = \frac{1}{6} \cdot \frac{9}{(101.3)^2} = .00015$. $\therefore s = .00015$. Checking, $v = c\sqrt{rs} = 101.3 \times 2.45 \times .01225 = 3.04$. If greater accuracy is required, assume a new slope slightly less than $s = .00015$ and try again.

The Venturi Meter.—This is an apparatus for determining the rate of discharge of water through pipes, by inserting the meter in the pipe line

Fig. 9.—Venturi Meter.

1 connecting it, by pressure pipes, to a register. The principle on which it based was discovered by J. B. Venturi, and his experiments were followed Bossut, Castel, Herschel and others. The apparatus is illustrated in 9, and consists of a short pipe V , of comparatively small diameter, called *venturi*, joining a converging frustum of a cone or mouthpiece M , with a diverging conical frustum D ; these three pipes being inserted in the pipe PP , with the water flowing in the direction indicated by the arrows. Surrounding the *venturi* V , is an air chamber, the cast-iron shell separating air chamber from the *venturi* being pierced with a few small holes, carefully drilled, leaving sharp, square edges on the inside face of the *venturi*.

Venturi discovered that when water flows through such a converging mouthpiece and a narrow *throat*, V , and then expands into a diverging tube or bell, D , there is a decided *decrease* of water pressure against the inside of the conduit from the beginning of the mouthpiece to the *venturi*, at which point it is a minimum, and then a decided *increase* in pressure from the *venturi* to the end of the diverging tube D . He correctly interpreted the cause of this reduction of pressure at V as due to a partial vacuum at o , just beyond the *venturi*, caused by the jet of water expanding from the throat along the tube D . In fact, not only is the pressure at the *venturi* greatly reduced, as in Fig. 11, but with high velocity of discharge the pressure changes, sometimes, from positive to negative, actually causing a *suction* in the air chamber at the *venturi*.

Mr. Herschel has clearly demonstrated that the differences in pressure at the beginning of the mouthpiece and at the *venturi* increases with the velocity of flow, and has established, by numerous experiments, a relation or relations between the two so that, knowing the difference in pressures at the two points, for a given meter, the discharge can be determined.

The Meter Register, indicated in Fig. 9, automatically records the discharge directly, in gallons, cubic feet or pounds—per second, minute, hour or day. The register is controlled by the pressures, or difference of pressures, in the pressure pipes leading from the meter.

The Manometer (Fig. 10) is a cheap device and not automatic as a constant recorder. It is a portable instrument that can be attached to any meter tubes on the pipe line and the rate of flow determined by reading the gauge, which has been graduated to "cubic feet per second," or "gallons per day," etc., based on difference of pressure in the connecting pressure tubes.

Fig. 10.
Manometer.

Piezometer tubes form a very simple device for measuring the pressure and flow in pipe lines and *venturi* meters. These are glass and iron tubes inserted at the required points along the line by "tapping" the pipe so that water will rise in the piezometers to the hydraulic gradient, or line of no pressure. Let PM , PV and PD be glass piezometers inserted at points M , V , and D , Figs. 11 and 12. Each figure shows the hydraulic grade line (1)

Fig. 11.
Pressure at the *venturi*.

Fig. 12.
Suction at the *venturi*.

for a uniform section of pipe, and (2) with the *venturi* meter inserted in the pipe line. If there is no meter in the pipe line, that is, no contraction of area, the H. G. L. will be a straight line on a falling grade in the direction of the flow, but may be considered as "level" for such a small distance as the length of the meter would occupy, as far as the present discussion is concerned; in other words, the loss of head for this distance would be practically zero. If now the meter is inserted in the pipe line, the H. G. L. will drop with a descending grade from M to V , and with an ascending grade from V to D ; but it will be noticed that it does not rise to its former level at D , there being a loss of head L in the flow through the meter from M to D . As the areas of the pipe at the piezometer PM and PD are equal, the velocities at these points are equal, hence the loss of pressure head L represents a total loss of head between those points, no part of it being compensated for by an increase in velocity. On the other hand, the loss of pressure head between M and V , represented by the difference in water levels in the piezometers PM and PV , is nearly all compensated for by the increased velocity of flow

at V over that at M , or in other words by the increased velocity head h , Fig. 11. Experiments on standard meters show that this velocity head represents about 98 per cent of the lost pressure head shown by the piezometers, the other 2 per cent being a total loss.

Where there is negative pressure or suction at the *venturi* (Fig. 12) the piezometer tube is bent in the form of a siphon and the amount of negative pressure head is measured by the height h_s of the column of water in the tube. This distance is laid off *below* the center of the *venturi*, as fixing the lowest point of depression in the hydraulic grade line. The velocity head is determined by the total change of pressure head as in the preceding description, taking into account of course the small percentage of actual loss.

Fig. 13 shows the standard dimensions of the *venturi* meter in terms of the length of the *venturi* V , assumed as unity; and it is claimed that, based

Fig. 13.—Standard Proportions of Venturi Meter.

on these proportions, for such a meter, with the diameter of the pipe ranging from one to nine feet, and with a velocity through the pipe ranging from one-half to six feet per second, the total loss of head in the mouthpiece will be about 2 per cent of the difference in pressure at these points. That is to say, the coefficient of velocity at the *venturi* closely approximates 98 per cent. The standard meter is proportioned with one main point in view, namely, to produce a marked increase in velocity at the *venturi*, with as little total loss as possible in the whole meter. In principle, it shows that if a pipe line is contracted at any point, the pressure head is reduced at that point, being partly converted into velocity head; and conversely, if it is expanded there is a *tendency* toward reconversion of velocity head into pressure head.

Leaving out the velocity of approach, the makers use the following formula for discharge:

$$q = ca \sqrt{(1.02 \pm) h} \dots \dots \dots (1)$$

In which q = discharge in cu. ft. per sec., or any other units;
 c = a constant or coefficient of velocity, determined by experiment;
 a = area of cross-section of *venturi* V , in sq. ft.;
 $(1.02 \pm) h$ = difference in height of piezometers PM and PV , in ft.;
 h = increase in velocity head at V over that at M .

Note that $(1.02 \pm) h$ is used for simplicity of illustration in keeping clearly in mind the relative value of the difference of velocity heads h . It is to be noted also that the *actual* velocity at the throat or *venturi*, V_1 , = $\sqrt{2 g h}$ + the velocity of approach, and not simply $\sqrt{2 g h}$.

Orifices, Tubes, Nozzles and Jets.—The *theoretic* discharge from an orifice is obtained by integrating or taking the summation of the discharge of each infinitesimal layer of water of transverse length x , thickness dy , and head y between the proper limiting values of the head. Thus, in computing Table 9, following, we have—

for rectangular orifice, submerged,
$$q = \int_{y=h}^{y=H} x dy \sqrt{2 g y} \dots \dots \dots (2)$$

which $x = b$; hence, theoretically,

$$q = \frac{1}{2} b \sqrt{2 g} (H^{\frac{3}{2}} - h^{\frac{3}{2}}) \dots \dots \dots (3)$$

for rectangular weirs, the upper head $h = 0$, $H = d$, $bd = a$; $\therefore q = \frac{1}{2} a \sqrt{2 g} d$.

Other forms of orifices are calculated in the same manner. The *actual* discharge and velocity are closely approximated by using *coefficients* of area contraction, velocity and discharge. Let—

- c_c = coefficient of contraction of jet;
- c_v = coefficient of velocity of jet;
- c_d = coefficient of discharge.

Then, Actual area of issuing jet at its smallest section = $c_d a$;.....(4)

Actual veloc. of issuing jet at its smallest section = $c_v v = 8.02 c_v \sqrt{h_0}$;.....(5)

Actual discharge of issuing jet = $c_d q = 8.02 c_d a c_v \sqrt{h_0}$;.....(6)

Coefficient of discharge = $c_d = c_a c_v$;.....(7)

The values of c_a , c_v and c_d for the various shapes and conditions of orifices, nozzles, jets, etc., are determined by experiment. The coefficient of contraction of area, c_a , for small standard orifices may be assumed at about 0.63; the coefficient of velocity, c_v , at about 0.98; and the coefficient of discharge $c_d = c_a c_v = 0.63 \times 0.98 = 0.62$. These values of the coefficients substituted in equations (4), (5) and (6) will give, approximately, the results which may be expected in practice.

Table 9, following, shows the discharge, q , from rectangular, triangular and circular orifices:

9.—TABLE OF DISCHARGES FROM ORIFICES.

(a) Orifices Submerged.

Function.	Water Surface 	Water Surface 	Water Surface 
(1)	(2)	(3)	(4)
a Area.....	bd	$\frac{bd}{2}$	$\frac{\pi d^2}{4}$
q Discharge.	$c_d \frac{1}{2} b \sqrt{2g} (H^{\frac{3}{2}} - h^{\frac{3}{2}})$	Not important *	$\left\{ c_d \pi r^2 \sqrt{2gH} \left(1 - \frac{r^2}{32H^2} \right) - \frac{5r^4}{1024H^4} - \frac{105r^4}{65536H^6} \dots \right\}$

And when the tops of the orifices touch the surface of the water, h becomes zero and we have, in each case, the following values:

(b) Water Surface at Tops of Orifices.

q	Discharge.	$c_d \frac{1}{2} a \sqrt{2gd}$	$c_d \frac{1}{8} b d \sqrt{2gd}$	$c_d \pi r^2 \sqrt{2g} r (0.96)$
---	------------	--------------------------------	----------------------------------	----------------------------------

$$* q = c_d \frac{b}{d} \sqrt{2g} \left(\frac{H^{\frac{3}{2}} d^2}{2} - \frac{H^{\frac{3}{2}} d^3}{6} - \frac{H^{\frac{3}{2}} d^4}{32} - \frac{H^{\frac{3}{2}} d^5}{80} \dots \right).$$

COMPARISON OF ORIFICES AND TUBES.

The standard orifice (Fig. 17) has sharp, vertical edges. From data above, $c_a = 0.625$; $c_v = 0.98$; $c_d = 0.6125$. The discharge can be increased by inserting the standard tube.

The standard tube (Fig. 18) is made just long enough so the expanding

Fig. 17.

Fig. 18.

Fig. 19.

Fig. 20.

Fig. 21.

jet completely fills its extremity. Around the contracted portion of the jet there is a partial vacuum, which may be tested by tapping the tube and inserting a glass piezometer, P , with its lower end immersed in a basin of water. The water will rise in the piezometer, indicating suction. The vacuum is produced by the particles of water or spray of the jet forcing the

air out of the tube. The effect is to increase the velocity and discharge, over that of the standard orifice. The values of c_v and c_d are about 0.81 or 0.82, average.

The *conical nozzle* (Fig. 19) is designed to increase the energy of the jet. The angle of divergence of the sides of the cone is about 13° or 14° for maximum discharge, when $c_v = 0.95$, nearly. Sometimes the outer end of the cone is provided with a short straight tube. The coefficient of velocity increases with the angle of the cone.

The *Venturi meter* is simply a compound tube (Fig. 20) and is explained on page 1173, etc.

The *flaring or bell-shaped mouthpiece* (Fig. 21) decreases the loss of head at entrance, usually called Entry Head (see page 1160) and is recommended for use at the intake end of pipe lines.

Weirs.—The weir is simply a water meter. Next to the Venturi meter (see page 1173) the standard weir is probably the most accurate device for measuring the flow of water. It is practically adapted to gaging the flow of small streams, creeks, canals, ditches, and the discharge from pipe lines and sewers.

The *standard weir* is a rectangular, vertical opening through which the surface water is allowed to discharge. The edges of the opening should be chisel-edged, the "crest" perfectly level, and the sides perfectly plumb. Fig. 22 represents a section of a standard weir with the water flowing over the crest. Note that the surface of the discharging volume describes a curve from a point of tangency T , distant D from the crest of the dam, the drop at the crest being s . Fig. 23 is a plan of the weir showing the length of crest l , and the side contractions e and e' of the flow, for the "end contractions" E and E' .

Fig. 22.—Sectional Elevation.

Fig. 23.

The standard weir is a weir with end contractions; the weir without end contractions is called the "suppressed" weir, because the end contractions are suppressed.

The *theoretic* discharge through a rectangular weir, neglecting velocity of approach, is obtained from the equations on pages 1175 and 1176, reducing to—

$$q = \frac{2}{3} L \sqrt{2g} H^{\frac{3}{2}} \quad (\text{no velocity of approach}) \dots \dots \dots (8)$$

in which q = discharge in cu. ft. per second;

L = length of weir, in feet (Fig. 23);

H = "surface level" head on crest, in feet (Fig. 22).

If it is desired to include velocity of approach,* v_a ($= \sqrt{2g h_a}$), this value must be inserted in equation (2), page 1175, before integrating; thus,

$$q = \int_{y=h}^{y=H} x dy \sqrt{2g y + v_a^2} \dots \dots \dots (9)$$

whence $q = \frac{2}{3} L \sqrt{2g} [(H + h_a)^{\frac{3}{2}} - (h_a)^{\frac{3}{2}}]$ (including velocity of approach) .(10)

in which h_a = velocity head of approach; and $h = 0$.

It is to be noted that these formulas, (8) and (10), are purely theoretical, and that little or no importance can be attached to them as they stand. But like all theoretic expressions, each forms a skeleton or groundwork upon which to build the more or less "empirical" formulas which are used in practice. The practical formulas are deduced from the above by supplying the proper coefficients, which are determined by experiments.

*The velocity of approach should be measured at the point T , Fig. 22. It should comprise generally the average velocity for some depth below the surface and not the "surface" velocity, which is often used; the latter may be close enough, however, in many instances. The surface velocity may be obtained by the surface-float method (Fig. 29); the average velocity, by the integrating float rod (page 1183), or by the current meter (page 1185), or by the Pitot tube (page 1183).

(a) FRANCIS' WEIR FORMULAS.

General formula applicable to any sharp-crested, surface weir:

$$q = 3.33 (L - 0.1 n H) [(H + h_s)^{\frac{3}{2}} - h_s^{\frac{3}{2}}] \dots \dots \dots (11)$$

in which q = discharge in cu. ft. per second;
 L = length of weir in feet;
 n = number of end contractions, as 0, 1 or 2;
 H = "surface level" head on crest, in feet;
 h_s = velocity head in feet = $\frac{\text{velocity of approach } v_a^2}{2g}$.

Formula (11) may be simplified to meet the following special cases:
 With velocity of approach—

$$\text{Contracted } \left\{ \begin{array}{l} \text{Both ends: } q = 3.33 (L - 0.2H) [(H + h_s)^{\frac{3}{2}} - h_s^{\frac{3}{2}}] \dots \dots (12) \\ \text{One end: } q = 3.33 (L - 0.1H) [(H + h_s)^{\frac{3}{2}} - h_s^{\frac{3}{2}}] \dots \dots (13) \end{array} \right.$$
